Bacterial confirmation of gonococcal arthritis

Sir, The case report 'Moraxella infectious arthritis: first report in an adult' by Rosenbaum et al.\(^1\) describes the unexpected culture of a species of Moraxella from the synovial fluid of a 42-year-old woman who was thought on clinical grounds to be suffering from gonococcal septic arthritis. However, the criteria used for identification were not sufficiently stringent to exclude the possibilities that the organism might in fact have been a strain of Neisseria gonorrhoeae or of Branhamella catarrhalis.

The isolate was described repeatedly as being a Gram-negative diplococcus. Lautrop\(^2\) notes that the short, plump Gram-negative rods of Moraxella may approach a coccal form, but stresses nevertheless that the rod-like shape of the genus is an important characteristic distinguishing it from the Gram-negative cocci within the family Neisseriaceae. The apparent absence of any rod-like forms in Gram-stained smears of the isolate is indicative of Neisseria or Branhamella, not Moraxella.

The isolate was reported as not utilising any sugars. We assume that the sugars tested were incorporated into the cysteine (sic) trypticase agar mentioned in the report, and that they included glucose, maltose, lactose, and sucrose. B. catarrhalis does not utilise sugars, and further tests may have indicated that the isolate belonged to this species. However, a more probable explanation is that the isolate was a strain of N. gonorrhoeae that failed to utilise glucose in cysteine trypticase agar, similar to strains described by White and Kellogg.\(^3\)

Perhaps the most disturbing aspect of the bacteriological investigations was the use of the API 20E system, designed primarily for the identification of members of the Enterobacteriaceae, for the characterisation of a fastidious Gram-negative coccus. In our laboratory known strains of N. gonorrhoeae (including a WHO reference strain) were identified as Moraxella sp. by this system. Other procedures for identification of N. gonorrhoeae, such as the use of specific fluorescent antibody or coagglutination tests, were apparently not carried out on the isolate.

In their introductory paragraph Rosenbaum et al. note the similarities between Neisseria gonococcus (sic) and Moraxella species, and they conclude their report with a comment on the need for bacterial culture to confirm a clinical diagnosis of suspected gonococcal arthritis. We emphasise that the identification procedures must include methods that are appropriate to the class of organism suspected, and that, if any doubt exists, confirmation of identity by a suitable reference laboratory should be obtained.

Immune deposits at the dermoepidermal junction in patients with rheumatoid arthritis

Sir, The deposition of immunoglobulin and complement components at the dermoepidermal junction in normal skin is well described in systemic lupus erythematosus (SLE).\(^1\) Studies in rheumatoid arthritis (RA) have yielded conflicting results with a frequency of 0-50%, reported,\(^2\) casting doubt on the diagnostic specificity of the 'lupus band' test. Reasons for such variation are not clear from inspection of the studies.

We have determined the prevalence of immune deposits at the dermal junction in 45 patients with RA. The study was designed to establish factors which might influence the development of deposits. Thus skin was sampled from the forearm of all patients, and from 34 an additional biopsy was taken from the leg to determine regional variation. Patients were studied as a group and by subdivision into those with articular disease alone and those with extra-articular manifestations. The influence of serological factors and of drug therapy was also examined. For comparison biopsy specimens were also taken from the arm and the leg of 14 patients with SLE and a miscellaneous group of 22 control subjects and patients with other rheumatological disorders. Sections of skin were processed for routine histological examination and by a direct immunofluorescent technique using rabbit antiserum to human IgG, IgM, IgA,
Bacterial confirmation of gonococcal arthritis.
