**Summary** A case of pachydermoperiostosis characterised by the presence of finger clubbing, periostosis, sweating of hands and feet is described. Modifications of capillaroscopic pattern and of arteriovenous anastomoses are reported. The periungual border and finger tip tissue showed diffuse endothelial hyperplasia, hyalinosis, and sclerosis with packing of collagen fibres. Electron microscopy showed hypertrophic and activated endothelia (numerous and hypertrophic Golgi complexes, several Weibel-Palade bodies, vesicles of micropinocytosis, and glycogen particles), the basal membrane thickened and reduplicated, perivasal infiltrate in superficial derma, reticulation and segmentary reduplication of basal membrane in arteriovenous shunt. In the perineural connective tissue numerous Luse bodies (long spacing collagen) were evident. The data indicate that in the early phase of pachydermoperiostosis morphological endothelial and collagen fibre abnormalities are present, though there is a normal peripheral blood flow.

Key words: endothelial activation; fibrous long spacing collagen.

Pachydermoperiostosis is a well recognised non-dominant autosomal disease1,2 characterised by a wide spectrum of symptoms (pachydermia, finger clubbing, bone periostosis, seborrhoea, arthritis or arthralgia, and acro-oesteolysis).3

Two forms of hypertrophic osteoarthopathy are known: a primary form—or pachydermoperiostosis of unknown origin—and a secondary form—or hypertrophic osteoarthopathy related to neoplastic or chronic diseases, or both, involving lung, liver, or heart.

This paper describes modifications of vessels and connective tissue in pachydermoperiostosis.

Accepted for publication 27 June 1988.

enlarged, but the legs were not deformed. No joint inflammation or effusion was present. An x ray examination showed slight periostosis of the diaphyses of the long bones (upper and lower limbs), but acro-osteolysis was not evident. The chest x ray and routine haematological tests did not show any abnormalities. After informed consent the patient underwent the following studies: thermography, photoplethysmography and strain gauge plethysmography, a Doppler study, capillaroscopy, scintography of the arteriovenous anastomoses, and a bone scintiscan (99Tc methylene diphosphonate). Arteriography was refused. As the patient complained of paraesthetic hand discomfort surgical reduction of the distal phalanges was carried out.

Biopsy specimens of the finger tips, periungual tissue, and dorsum of the hand were taken and studied by light and electron microscopy.

**Special studies**

Thermography did not show any signs of hyperthermia of hands and feet. Photoplethysmography and strain gauge plethysmography showed respectively a normal wave and a regular digital flow in all fingers, at room temperature and with cold (10°C for one minute) and heat (40°C for five minutes) testing. Doppler examination of the arteries of the upper and lower limbs did not show any significant changes. Nail bed capillaroscopy showed (a) thin, tortuous, and irregular capillaries with morphological heterogeneity of the loops and the presence of atypical elements ('scalloped loops'); (b) new capillary formation (thin calibre tortuous loops); (c) irregular distribution of loops along the periungual border (presence of three to four capillaries in a single papilla); and (d) sporadic ectasic loops with homogeneous dilatation on the venular tract. No flow abnormalities were observed (Fig. 1).

The arteriovenous anastomoses, measured by an indirect method (injection into the brachial artery of 0.5 ml 37–111 kBq 99mTc labelled human albumin microspheres of 20/40 nm diameter), were normal when compared with those of matched controls. Scintigraphs carried out at 10°C showed an abnormal accumulation of microspheres in the finger tips of

both hands (Fig. 2). A $^{99m}$Tc methylene diphosphonate bone scintiscan showed a slight pericortical concentration of the radionuclide along tibial and fibular, ulnar, and radial diaphyses.

Light microscopy examination of specimens from the finger tip and periungual zone (lesional skin) showed diffuse endothelial hyperplasia, more evident in the capillaries (Fig. 3), with partial occlusion of the vascular lumen. Capillary enlargement in the deep and interpapillary dermis was occasionally observed. An abundant pericapillary lymphohistiocytic infiltrate was always present. Hyalinosis and sclerosis, with thickening and packing of collagen fibres, were present in the connective tissue. The epidermis was acanthotic with a normal granular layer and thickening of the basal membrane. In the dermis the collagen bundles appeared to lose their outlines and fuse together. Sebaceous and eccrine glands appeared hypertrophic.

Electron microscopy demonstrated the presence of capillaries in the superficial dermis that were in some places ectasic and in others characterised by hypertrophic and activated endothelia, which brought about pseudo-occlusion of the lumen (Fig. 4). Endothelial activation was characterised by a rich granular pattern with numerous and hypertrophic Golgi complexes, abundant microfilaments, numerous Weibel-Palade bodies, vesicles of micropinocytosis, and glycogen particles (Fig. 5). The basal membrane of the capillaries was thickened and reduplicated (Fig. 4). The arteriovenous anastomoses showed a reticulation and a segmentary reduplication of the basal membrane with signs of endothelial activation (Fig. 6). Perivascular infiltrate was present in the superficial derma (Fig. 4).

In the perineural connective tissue, close to the arteriovenous anastomoses, numerous Luse bodies (fibrous long spacing collagen) were observed (Fig. 7). The deroepidermal basal lamina was normal.

The cutaneous biopsy specimen taken from apparently uninvolved hand dorsum showed qualitatively similar but less marked alterations than those detected in the finger tip and periungual zone, both with electron and light microscopy.

Discussion

The origin of pachydermoperiostosis is still unknown. In the last 20 years attention has been focused, with contradictory results, on the microvascular aspects of the disease. Some authors showed capillaroscopic abnormalities,6–7 segmental arterial abnormalities with obstructive phenomena,2–7 and increased venular fibrinolytic activity in the skin.8 Others detected an increased blood flow through the arteriovenous anastomoses and rapid filling of veins.9 Two authors described pachydermoperiostosis as having a normal blood flow.10–11 In the present case, which may be regarded as being in the early phase of the disease because of the recent onset, we found a normal peripheral blood flow judged by thermographic, plethysmographic, capillaroscopic, and Doppler studies.

Capillaroscopy showed irregular capillaries with ectasic venular loops; these abnormalities, together with the pathological alterations observed in this phase of the disease, indicate a microangiopathy and a tendency towards vascular neoformation. These alterations and the described endothelial activation may be induced by an unknown factor,12 as already suggested for systemic sclerosis.13

A division of the clinical course of pachydermoperiostosis into two phases has been proposed6–7: the first phase, early active with increased blood flow, and the second, late inactive with reduced blood flow. It is difficult to classify our patient in the first phase of pachydermoperiostosis as we found normal peripheral blood flow with plethysmography, Doppler studies, and capillaroscopy. It is possible that our case is in a phase characterised by pathological alterations that immediately precede the phase with increased blood flow. Scintigraphy showed a normal patency at room temperature, but the cold test at 10°C showed an abnormality in arteriovenous anastomoses functioning similar to that in Raynaud's phenomenon.14 It may be that this functional alteration is related to the cellular modifi-

cations observed in the dermal microvessels. In fact the ultrastructural investigation showed that (a) endothelial cells, whether of capillaries or of arteriovenous anastomoses, are activated. This could account for the partial occlusion of the capillary lumen; (b) numerous Weibel-Palade bodies are present; (c) there is thickening and diffuse reduplication of the basal membrane of the capillaries, even those that are ectasic, as well as reticulation and segmentary reduplication of the basal membrane of the arteriovenous anastomoses; (d) there is always the presence of a dense perivascular lymphocytic infiltrate.

These ultrastructural findings observed in the dermal microvessels are frequently found in the course of microangiopathy of different origin—for example, scleroderma.14 In addition, in our case numerous Luse bodies were found in dermal perineural connective tissue. These correspond to collagen fibrils with a periodicity that differs from that of normal collagen.5 15 They are not normally present in the healthy dermis, but they may be found in sclerodermic skin and in many other diseases.15 An increase in tissue concentration of glycosaminoglycans seems related to the presence of Luse bodies.16
In conclusion, our data indicate that in the early phase of pachydermoperiostosis morphological endothelial and collagen fibre abnormalities are present, while there is a normal peripheral blood flow.

We wish to thank Dr W Grassi for his helpful contribution in describing the results of capillaroscopy.
