increase haemoglobin synthesis and erythropoesis. Further clinical and fundamental research is warranted to establish the possible beneficial effects of (oral) iron chelation treatment on RA activity and the anaemia of chronic disease.

Tramsa and seronegative spondyloarthropathy
Sir: We have always been intrigued by the topic of trauma and seronegative spondyloarthropathy because of its many implications. Recent reports in the Annals have been particularly stimulating and shown how much work is still needed in this area. We decided to contribute to the subject by considering the following question: does a trauma immediately precede the onset of seronegative spondyloarthropathy? (2) Does a trauma immediately precede the onset of a peripheral arthritis in a patient with seronegative spondyloarthropathy? (3) Is there an association between trauma, onset of arthritis, and HLA-B27?

We studied 209 patients affected by different forms of seronegative spondyloarthropathy: 138 with peripheral arthritis, 49 with arthritis during ulcerative colitis, and 22 with ankylosing spondylitis. The prevalence of HLA-B27 was 34% (71 patients: 45 with psoriatic arthritis, six with ulcerative colitis, and 20 with ankylosing spondylitis). In two cases (1-0%) an articular trauma immediately preceded the onset of the seronegative spondyloarthropathy. In both cases the HLA-B27 phenotype was absent.

When we extended the definition of trauma to include every acute disorder that immediately preceded arthritis onset, even extra-articular disorders, 11 more patients were identified (5% of the total). Surgeons had been called in five cases, spontaneous abortion had occurred in two, and thrombophlebitis, bulous colica, myocardial infarction, and phosphoric ester intoxication in one case each respectively. Three of these 11 patients had the HLA-B27 phenotype.

We then evaluated the possibility that HLA-B27 positivity was associated with the onset of arthritis following trauma. As shown in the table, no significant relation was found. We then considered from among the total number of patients those with a peripheral arthritis (130 patients: 102 with psoriatic arthritis, 23 with ulcerative colitis, five with ankylosing spondylitis). The prevalence of HLA-B27 was 25-4% (37 patients: 27 with psoriatic arthritis, three with ulcerative colitis, three with ankylosing spondylitis). An articular trauma immediately preceded the onset of peripheral arthritis in three cases, all HLA-B27 negative (2-3%). When the extended definition of trauma (previously mentioned) was used 10 more subjects (7-7%) were included (the above patients plus the exception of one who had had surgery). In three cases HLA-B27 was positive. Again, no significant association was found between the presence of HLA-B27 and peripheral arthritis onset after trauma (Fishers's exact test: two tailed p=0.00; uncorrected χ²=0.04; p=0.84).

Therefore on the basis of our results we can conclude that: (1) articular trauma can immediately precede seronegative spondyloarthropathy, though the percentage of cases in which this occurs is small; (2) trauma defined as every acute disorder immediately preceding seronegative spondyloarthropathy onset is detectable in a higher percentage of cases; (3) HLA-B27 does not seem to predispose to arthritis onset following trauma in patients with seronegative spondyloarthropathy.

Habitual knuckle cracking and hand function
Sir: In a recent survey Castellanos and Axelrod evaluated 301 consecutive outpatients at Mount Carmel Mercy Hospital to determine whether habitual knuckle cracking is a risk factor for hand dysfunction. They found no relation with osteoarthritis, but noted that 'knuckle crackers were likely to have hand swelling and lower grip strength' and concluded that 'habitual knuckle cracking results in functional hand impairment'. I believe they have not established cause and effect in these interesting correlations.

Not everyone can crack their knuckles. Some do so with ease, whereas others are quite incapable of performing the feat. No one has determined how the joints of these groups differ. It is quite possible, for instance, that metacarpophalangeal joint laxity may both facilitate knuckle cracking and impair hand function. As this hypothesis implies that hand swelling and diminished grip occur secondary to articular structure rather than abuse, it may be that nervous citizens of Detroit can continue to crack their knuckles without fear of injury.

"Will cracking my knuckles hurt my hands?" remains a common gambit when a rheuma-tologist is identified, as such among new acquaintances striving to make conversation. I still believe that the answer to this question is no, but perhaps it is time that we really found out.
