Cricothyroid arthritis in a child with familial Mediterranean fever

Sir: We describe for the first time the occurrence of cricothyroid arthritis in a girl who first presented with migratory polyarticular arthritis but eventually developed the classical features of familial Mediterranean fever. A 9 year old Palestinian Arab girl was admitted in January 1985 with fever and migratory polyarticular arthritis of the large joints. The heart was normal. The erythrocyte sedimentation rate was 110 mm/h and the anaesthetic test was 400 Todd. A diagnosis of acute rheumatic fever was made and treatment was started with secondary prophylaxis. During the following six years she had several episodes of arthritis which were interpreted as recurrence of acute rheumatic fever due to irregular prophylaxis, and occasional fever and abdominal pain.

In January 1985 the girl was admitted with fever and arthritis of both elbows and the right wrist. The previous episodes of the developed arthritis involved the cricothyroid joint. The diagnosis was verified by indirect laryngoscopy. She also developed arthritis of the interphalangeal joints of both hands. She became better after five days of aspirin therapy. Two months later she had another similar episode of transient arthritis of the cricothyroid and interphalangeal joints. During the following three years she had several episodes of fever and abdominal pain, with the frequency progressively increasing to one to two attacks a week. She also developed arthritis of the ankles associated with erysipelas-like erythema. Family history revealed that her mother had a bilateral auricular and two sisters had similar recurrent episodes. Prophylaxis with colchicine was effective in decreasing the frequency of febrile and painful episodes; during the past 12 months she had only three episodes of abdominal attacks and one episode of transient arthritis of the left ankle.

The synovial attack of familial Mediterranean fever typically appears as acute monoarthritis affecting a large joint of the lower extremity.1,2 Involvement of the small joints, including the temporomandibular, sternoclavicular, and metatarsophalangeal joints, has been described in patients with familial Mediterranean fever,1,2 whereas involvement of the interphalangeal joints has been reported to be most unusual.3 Cricothyroid arthritis in the course of familial Mediterranean fever has not been previously described.

The presentation with migratory polyarticular arthritis, the involvement of the interphalangeal joints, and the long period before the appearance of the classical manifestations of familial Mediterranean fever are other unusual features in this patient.

Trauma and seronegative spondyloarthropathy

Sir: We would like to offer what we believe to be a necessary reply to Professor Panayi's letter published in the Annals.1 Professor Panayi considers that in the two B27 positive patients we described, who developed peripheral arthritis immediately after trauma,2 physical injury and the onset of peripheral arthritis were only coincidental. The first case presented in his opinion, a reactive arthritis of the knee, following gastroenteritis, and the second case, arthritis of the knees begun by chance after the trauma. If other articles on this subject1-6 are not taken into account this may seem to be the most logical conclusion, partly because no evidence of causality may be produced other than the immediate onset of peripheral arthritis after trauma, and the lack of an infective trigger. Winsnieski and Masson et al have reported other cases of peripheral arthritis in B27 positive subjects immediately after physical injury. In some of these, like our patient 1,2 there was also urethritis with negative urethral smear and culture, in addition to arthritis. Our patient also had a diarrhoea with negative stool culture, which subsided in two days without any treatment. In 1982 Jacobs et al reported that five of their 58 patients with juvenile onset B27 positive spondyloarthropathy had a trauma severe enough for a doctor to be consulted before the onset of peripheral arthritis.3 In 1988 we reported these five positive subjects who had never had pain to peripheral joints before, but developed an erosive peripheral arthritis of the right hip shortly after a severe physical injury to the same joint.4 The rapid evolution of the destructive process, which is not usual in erosive arthritis of seronegative spondyloarthropathy, provides further evidence in favour of the triggering role of trauma.

In conclusion, the articles published on the subject suggest that as in psoriatic arthropathy,5,6 physical injury may, in B27 positive subjects, trigger the onset of a peripheral arthritis predominantly involving the intermediate joints. We hope that others will report similar cases and perform studies on the synovial fluid and blood of patients with B27 associated peripheral arthritis following trauma, in an attempt to understand the pathogenetic mechanisms. We appreciate the comments of Professor Panayi and thank him for drawing attention to this topic to seronegative spondyloarthropathy.

Chondroprotective drugs and osteoarthritis

Sir: I read with interest the leader article by Doherty on 'Chondroprotection by non-steroidal anti-inflammatory drugs' published in last month's Annals. Although I am in general agreement with the views expressed by Dr Doherty, I raise some issues which I consider deserve further comment.

In his article Dr Doherty questions the relevance of certain laboratory derived data on non-steroidal anti-inflammatory drugs (NSAIDs) to their clinical use in osteoarthritis. He considers the standard for assessing these drugs to be the long term symptomatic and functional improvement in patients 'rather than individual biochemical or structural characteristics'. It should be noted, however, that most NSAIDs are also powerful analgesics and may effectively relieve the symptoms of osteoarthritis without necessarily influencing its progression. Pain relief and improvement of joint mobility are thus inadequate criteria for distinguishing between NSAIDs acting only as an analgesic and an NSAID which is also positively influencing the underlying osteoarthritis disease. More objective methods of clinical assessment of patient response to drug treatment are therefore necessary, before this matter can be resolved. Such methods are presently under investigation, and promising findings have been reported with biochemical markers of cartilage metabolism in synovial fluid4-9 and serum,6,9 x ray microfocal (Buckland-Wright et al, unpublished data).
