Mixed connective tissue disease presenting as a left sided pleural effusion

Y Ilan, A Ben-Yehuda, E Okon, R Breuer

Abstract
Mixed connective tissue disease (MCTD) usually occurs in women aged 13–50 years. Pleural effusion is rarely the presenting feature of this disease. The case is reported here of a male patient with MCTD who presented at the age of 79 years with a left sided pleural effusion.

(Med Dis 1992; 51: 1157–1158)

Mixed connective tissue disease (MCTD) is a syndrome characterised by a combination of clinical features similar to those of systemic lupus erythematosus, scleroderma, polymyositis, and rheumatoid arthritis, and an unusually high titre of circulating antibodies to ribonucleoprotein.1

The mean age of presentation is 31–9 years and 80% of patients are women.1 2 Pulmonary disease is usually interstitial and occurs in 80% of patients with MCTD.

The case is reported of a 79 year old man with left sided pleural effusion as a result of MCTD.

Case report
A 79 year old white man presented with a three month history of dyspnoea on exertion, weakness, and pleural effusion. He had mild non-insulin dependent diabetes mellitus and benign hypertrophy of the prostate. He was not aware of any cardiopulmonary disease.

On physical examination the patient had normal vital signs. Sclerodactyly of the hands was prominent and Raynaud’s phenomenon was induced by cold water. Skin examination showed leathery-like red areas over his arms, face, and chest. Dullness on percussion, decreased tactile fremitus, and breath sounds were noted in the posterior aspect of the left lung. A 3/6 systolic murmur was heard over the fifth intercostal space and mid-clavicular line. The remaining physical examination was normal.

Laboratory examination showed a sedimentation rate of 130 mm in the first hour. Urine analysis was normal. Haemoglobin was 129 g/l, packed cell volume 0.41, and white blood cell count 13.5x10^9/l with a normal differential. Kidney and liver function tests were normal. The creatinine kinase level was 305 U (normal range 50–100 U). Antinuclear factor was strongly positive and consisted mainly of antibodies to ribonucleoprotein. There was no antibodies to DNA. Thyroid function tests were normal. Arterial blood gases showed pH 7.4, Paco2 75 mmHg and Paco2 37 mmHg. A chest radiograph showed left sided pleural effusion and no parenchymal infiltrate (fig 1). A skin test with purified protein derivative (5 TU) was negative. The pleural effusion was an exudate with protein levels of 45 g/l and 1.5x10^9/l leukocytes, 80% of which were mature lymphocytes with no malignant cells, and negative acid fast stain and tuberculosis culture. The pleural biopsy sample (fig 2) showed an extensive inflammatory lymphoplasmacytic infiltrate affecting the muscle with changes in the muscle fibres. There was fragmentation of single muscle fibres, variation in size, fibre loss, and focal fibrosis. In some foci macrophages were seen ingesting fragments of muscle tubes. No granulomata nor signs of malignancy were seen.

The muscle biopsy sample from the quadriceps (fig 3) showed foci of necrotic muscle fibres with phagocytosis of the sarcolemma. Other areas showed basophilia of the hyaline contents of the fibres with proliferation of sarcomemmal nuclei. Small aggregates of lymphocytes and mononuclear cells were also seen around necrotic muscle fibres. The bone marrow was normal. A gallium bone scan was also normal. A chest computed tomography scan showed a large left pleural effusion.

The patient was treated with isoniazide and rifampicin for nine weeks with no clinical or radiological response. Treatment with prednisone (40 mg/day) was then begun with an improvement of the symptoms and partial resolution of the pleural effusion.

Figure 1 Chest radiograph showing a left sided pleural effusion with normal heart size and no parenchymal findings.
During follow up over the next six months his plural effusion resolved almost completely, the erythrocyte sedimentation rate decreased to 25 mm in the first hour, and creatinine kinase decreased to normal concentrations.

Discussion
The combination of sclerodactyly, chemical and histological myositis, and a high level of antinuclear factor, most of which was antibodies to ribonucleoprotein led to the diagnosis of MCTD in this patient. Malignancy such as lymphoma or metastatic spread to the pleura are unlikely if the normal computed tomography scans and the negative pleural fluid cytology and tissue biopsy sample results are considered. Tuberculosis is unlikely as there was no response to treatment for this disease and the acid fast stains and cultures were negative.

The presentation of MCTD as a large left pleural effusion in our patient is unusual. Pulmonary disease occurs in 25–80% of patients with MCTD. Sixty five per cent of these patients are asymptomatic; the others may have dyspnoea, chest pain, or cough. Radiologically 85% of patients with pulmonary disease show bilateral interstitial infiltrates. Small pleural effusions were found in 6% of patients in one isolated series, but accompanied pulmonary infiltrates in all patients. Pleural effusion without interstitial pulmonary disease has been reported in one patient. This and the present report show that pleural effusion can be the presenting and the only lung manifestation of MCTD.

It is possible that the fluid accumulation and the dyspnoea are part of the serositis in this disease, but they could also result from the adjacent inflamed intercostal muscles. The observed improvement of the pleural effusion in response to treatment with glucocorticoids is expected to occur in patients with MCTD, a disease which responds to steroid treatment, and such treatment should be considered in any patient with an unexplained pleural effusion.

Another unusual feature of the disease in this patient is the age of onset. Most patients with MCTD are women and the mean age of onset is 31–9 years.1 2

In conclusion the case has been reported of a patient with pleural effusion eventually diagnosed as having MCTD. This case shows the importance of reaching this diagnosis and suggests that MCTD should be included in the differential diagnosis of treatable pleural effusions.

Figure 2  Pleural biopsy sample showing the variation in size and fragmentation of many intercostal muscle fibres. Note areas of fibre loss with fibrosis and extensive inflammatory infiltrate of mainly lymphocytes and plasma cells. Haematoxylin and eosin stain.

Figure 3  Muscle biopsy sample from quadriceps showing foci of necrosis of the fibres with phagocytosis of the sarcolemma. Haematoxylin and eosin stain.

Mixed connective tissue disease presenting as a left sided pleural effusion.
