a two year history of recurrent painful violet erythema nodular lesions associated with high levels of RF (latent; range 1048–2000 U/ml). She denied asthma, weight loss, fever, and had no respiratory or articular complaints.

On physical examination many scattered, painful, tender and slightly raised violet subcutaneous nodules were found on the posterior aspects of both calves. The patient was afebrile. Results of cardiopulmonary and abdominal explorations were unremarkable. White blood cell and platelet count were normal. The haemoglobin was 126 g/l and erythrocyte sedimentation rate 18 mm/1st h. Urea nitrogen, creatinine, glucose, bilirubin, aspartate transaminase, alkaline phosphatase, cholesterol, triglycerides, calcium, and phosphorus were all normal. A positive purified protein derivative skin test, antinuclear antibodies, cryoglobulins, and serum complement (C3 and C4) were unremarkable. Serum RF determined by turbidimetric immunoassay was 2048 U/ml (Quantex RF plus—latex; WHO units). Rheumatoid factor determined by haemagglutination on slide (modified Waaler-Rose procedure) was 256 U/ml (Celgard AR; Biokit SA, Spain; WHO units).

Chest films showed a fibroproductive pattern affecting both upper lung lobes without paratracheal or perihilar adenopathies. Microscopic examination of three sputum specimens stained by Ziehl-Neelsen’s method disclosed no acid-fast bacilli. A wedge biopsy of one skin nodule was performed and pathological examination disclosed a granulomatous panniculitis consistent with erythema induratum (figure). Ziehl-Neelsen and auramine-rhodamine stains were negative. Sputum cultures in Löwenstein-Jensen medium grew M tuberculosis.

Specific daily treatment with rifampicin 600 mg, isoniazid 300 mg, and pyrazinamide 1500 mg was started and continued for two months. Rifampicin and isoniazid was continued for four more months at the same dose. The two Mantoux tuberculin skin tests (5 tuberculin units of purified protein derivative) performed while the patient was receiving chemotherapy were negative. At the end of the first, third, and sixth months of treatment, RF had decreased to 600, 200, and 44.2 U/ml respectively. The patient remained asymptomatic, and skin lesions healed leaving a pigmented scar.

Erythema induratum, included in the tuberculosis, is not a ‘true’ manifestation of skin tuberculosis because acid-fast bacilli are not found. Although M tuberculosis has occasionally been isolated when erythema induratum coincides, most experts support its aetiologic role. Nodular vasculitis is a form of multifocallobular panniculitis that may coexist with a tuberulous focus (erythema induratum or Bazin) or may not (nodular vasculitis erythema induratum complex).

Throughout the two year follow up of our patient no nodule became ulcerated and lesions healed spontaneously. Rheumatoid factors in low titers are found in a small percentage of young adults. A high prevalence of RF is also found in patients with chronic infections, such as syphilis, leprosy, and tuberculosis. These observations have suggested that extensive or persistent exposure to antigens and immune complex formation induces the synthesis of RF. M tuberculosis organisms can induce the production of RF, and several reports have demonstrated the autoimmuneigen capacity of some proteins of this microorganism, particularly heat shock protein 60. Immune complexes seem to have an important pathogenic role in nodular vasculitis. They have been found in patients with Henoch-Schönlein purpura associated with active tuberculous infection. It should be pointed out that sarcoid and autoimmune diseases with increased RF levels, such as rheumatoid arthritis, Sjögren’s syndrome, cryoglobulinaemia, and autoimmune liver disease, were excluded. Moreover, after treatment was started, RF progressively fell to nearly normal values.

The persistent negativity of the Mantoux skin test deserves a special mention. It is unlikely that the patient had disseminated tuberculosis or any other immunosuppressive condition. A negative Mantoux skin test has been described in patients with erythema induratum. There is no doubt about the importance of the skin biopsy as it allows histological demonstration of erythema induratum and helps to establish the differential diagnosis with erythema nodosum, syphilis, foreign body granuloma, and skin tuberculosis. Finally, we strongly believe that the finding of erythema induratum should prompt a diagnostic search for pulmonary or extrapulmonary involvement of tuberculous infection.

**CREST syndrome with pericardial but not peripheral calcification**

Sir: The CREST subgroup of systemic sclerosis is a mild or slow progressive form of the disease characterised by calcinosis, Raynaud’s phenomenon, oesophageal dysfunction, skin thickening, and sclerodactyly. Anticentromere antibodies detected on the Hep-2 substrate appear highly selective for this group of patients. We report the first case of CREST syndrome with pericardial calcification. A 56 year old white female smoker presented to her general practitioner with breathlessness in August 1989. She had a history of asthma, which had been controlled with inhaled steroids. She had a eczema of the feet which was treated with topical steroids. She had a history of Raynaud’s phenomenon and had been referred to a rheumatologist. She had a history of dysphagia which was treated with cisapride having no improvement. She was in atrial flutter with 2:1 block and had signs of ‘mild congestive heart failure’. The jugular venous pressure was raised 9 cm. A chest radiograph showed a cardiothoracic ratio of 58% with upper lobe vascularity. She was anticoagulated and cardioverted but atrial flutter recurred, and her ventricular rate was controlled with verapamil, digoxin, and a diuretic. The patient had a six year history of Raynaud’s phenomenon and was noted to have facial telangiectasia and mild sclerodactyly. Further investigation showed a positive anticentromere antibody and negative antinuclear and ScI-70 (topoisomerase 1) antibodies. A barium study showed markedly reduced oesophageal motility. A diagnosis of CREST syndrome was made, though no calcification had been detected either clinically or radiologically. She was treated with amiodarone and was given a calcium channel blocker. Although there was improvement in her dysphagia, the jugular venous pressure remained raised. In March 1991 she reported increasing shortness of breath on exertion and swelling of the legs. Her jugular venous pressure was 8 cm raised with a positive Kussmaul’s sign and pulsus paradoxus of 30 mmHg. A lateral chest radiograph showed marked pericardial calcification (figure) that had not been apparent on previous posteroanterior views. There was no history of tuberculous or tuberculous contacts. The possibility of an operation to relieve her tamponade was discussed, but the patient refused.
Within three months, however, she underwent cardiac catheterisation with simultaneous right and left heart pressure measurements which showed the characteristic dip and plateau configuration of constrictive pericarditis. A pericardectomy was performed and she made an uneventful recovery. On returning to full activity she again complained of shortness of breath on exertion. Physical examination and chest radiography showed no evidence of residual pericardial constriction. Spirometry, however, show an obstructive picture with a forced expiratory volume in one second of 0.85 litres and forced vital capacity of 1.6 litres. Her symptoms improved considerably with bronchodilator treatment. Respiratory function tests showed reduced lung volumes and an obstructive defect. The peak flow improved from 145 to 200 l/min (predicted 319 l/min) after nebulised salbutamol. The corrected transfer factor was only marginally reduced, making significant pulmonary vascular disease unlikely.

Our patient's deteriorating exertional dyspnoea and increasing oedema in 1991 were due to pericardial constriction and once this had been surgically relieved the presence of obstructive airways disease was unmasked. Pericardial disease occurs in about 50% of patients with systemic sclerosis and only slightly less commonly (38%) in patients with CREST. Only a third of these patients are symptomatic, however. As far as we know, this is the first reported case of calcific constrictive pericarditis in the CREST syndrome and is particularly unusual in that our patient had no evidence of peripheral calcification.

Lung involvement in systemic sclerosis was recognised shortly after the original description of the disease and is found with a similar prevalence in patients with CREST. Although large airways obstruction in CREST syndrome and systemic sclerosis has been well described, response to bronchodilator treatment is poorly documented. A small number of children with systemic sclerosis have had bronchodilator responsive obstructive airways disease. Our patient's incomplete but appreciable response and symptomatic improvement suggests that bronchodilators may be helpful in this situation.
