Microcirculation in ankylosing spondylitis

It was interesting to read the paper by Beauvais et al reporting two cases of ankylosing spondylitis (AS) with cutaneous vasculitis and IgA nephropathy1 emphasising the possibility of vascular involvement in AS. We wish to emphasise this aspect by the evaluation of microcirculation in AS using nailfold capillaroscopy.2

Forty six patients were enrolled in this prospective study, divided into 32 AS patients (fulfilling the revised New York criteria),3 mean age 38 years. Twenty eight were HLA B27 positive, and there were 14 control patients (disc herniation) mean age 34-6 years.

Capillaroscopic findings evaluated by the same investigator (JCR) (unaware of the diagnosis in most of the cases) were classified into five groups: normal, minor dystrophies (characterised by more than 15% tortuosity); occasional by finger tips degree of peri- capillary environment); microangiopathy (this pattern represents--a qualitative element represented by major dystrophies like mega- capillaries with irregular diameter, tortuous meandering or bushy capillaries—and quanti- tative element (reduction of loop number in the nailfold distal row less than 9 per mm), and stasis (characterised by a dark blood flow, sometimes granular, with low speed and regular enlargement of the two branches).

Statistical analysis used Fisher's exact test for normal and minor dystrophies on the one hand, and oedema and microangiopathy on the other.

The results, summarised in the table, show more frequent capillaroscopic abnormalities in the AS group compared with controls, for the oedema and microangiopathy patterns (p < 0.01), whereas there was no difference for minor dystrophies. No differences were found in terms of age, disease duration rheumatological and extra articular manifestations (skin, kidney, gut) or biological param- eters (CRP, serum IgA) between AS patients with microangiopathy (n = 5) and AS patients with a normal capillaroscopy (n = 9).

Nailfold capillaroscopy is a simple, non invasive and producible technique.2 In this study minor dystrophies are seen with the same prevalence in both groups. A specific capillaroscopic pattern of AS does not seem to exist. Conversely, this study shows an increase of abnormalities like pericapillary fusions (oedema) (due to an inflammatory reaction), and microangiopathy. These findings are in accordance with the reports of clinical vasculitis associated with AS, such as cutaneous vasculitis4-6 associated with renal or gut involvement, or large vessel vasculitis, Takayasu's arteritis7 or polyarteritis nodosa.8-10 Histological studies have also revealed the possibility of vascular in-

Cervical neuropathology in rheumatoid arthritis

I read with interest the article on the neuropathology of the brainstem and spinal cord in long standing, severe, rheumatoid arthritis1 and the authors' assessment of the pathological mechanisms involved in this association.2

They conclude that the major mechanism of damage is pressure on the anterior aspect of the cord by the skeletal elements making up the neural canal due to the subluxation deformity of the neck. However, they seemed to reach an uncertain conclusion about whether neural damage was seen in the posterior part of the spinal cord.

In 1982 we reported a series of patients with manubrio-sternal joint subluxation due to rheumatoid arthritis, and noted that this deformity was closely associated with major deformities in the cervical spine.2

We postulated that both deformities resulted from chronic forward flexion of the head on the trunk leading to both cervical (manubrio-sternal) and posterior (cervical spine) joint subluxation. This would agree with the hypothesis put forward by Henderson et al that the damage to the cord is due to forced flexion of the neural canal over the spinal cord, leading to anterior compression and more seriously to chronic stretching and fissuring of the posterior part of the cord.

In both Henderson's paper and in ours the straight position of the neck as well as in the anterior aspect of the chest) by attempting to reduce the forward flexion so typical of these patients.

AUTHOR'S REPLY Dr Rooney's observation of patients with rheumatoid arthritis that manubrio-sternal subluxation is associated with chronic flexion of the neck helps to explain our unexpected histological findings in nine patients who came to necropsy, which we reported in our recent article.1 We concur with Dr Rooney's hypothesis that damage to the spinal cord results from flexion over a deforming mass, such as a subluxed odontoid process or pannus formation. The shear caused by the ventral deformation is transmitted dorsally, and correspondingly results in dorsal cord injury.

The fixed neck flexion which Dr Rooney observed helps to explain why there was selective injury to the axons of the cuneate fasciculi. Several authors have suggested that mechanical injury to the brachial nerve roots may occur as they are repetitively pulled taut around the pedicles during flexion of the neck.4 We believe that chronic stretch injury
