Systemic sclerosis and organic solvents: early diagnosis in industry

In 1957 Rein and Walder described the first cases of systemic sclerosis (SS) after contact with organic solvents. An increasing number of cases have subsequently been reported, mainly involving aliphatic hydrocarbons (vinyl chloride, perchloroethylene, trichloroethylene), and 20 cases related to aromatic hydrocarbons (benzene, toluene, xylenes, white spirits and diesel). Aromatic amines (cyclohexylamine and m-phenyl-enediamine) and formaldehyde derivatives were involved in about 10 cases.1-3

Our 56 year old patient developed SS with skin, lung and pericardial involvement after intense and prolonged exposure to trichloroethylene (atmospheric hydrocarbon), heptane (aliphatic hydrocarbon), dimethylbutyl phenyl diamin and formaldehyde derivatives, which were non chlorinated hydrocarbon and sulphated substances was also assessed.

For 23 years he had worked in the rubber fabrication sector of a tyre factory. After a period of eight years he developed progressive thickening of the skin of the fingers, Raynauld’s phenomenon and progressive effort dyspnée. He was first seen by us in May 1981 because of dyspnée on minimal exertion.

Clinical findings on admission were sclerodactyly, mild generalised cutaneous sclerosis (more intense on both shoulders and one of the hands) and telangiectasia. Despite his small trunk and trunk palpebral telangiectasia. A trunk skin biopsy showed a severe sclerosis of the dermal collagen, with few fibroblasts, sclerosis of the sweat glands and subdermical dermis, with poor vascularity and seita thickening of subcutaneous tissue. Fine crackles were present in both lung bases. A chest radiograph showed cardiomegaly. Echocardiography revealed a small pericardial effusion and enlargement of the right cavities with mild tricuspid insufficiency that yielded a pulmonary arterial hypertension of 46 mm Hg. Cardiac catheterisation showed it to be pre-arteriolar. Respiratory function tests showed moderate-severe restriction, (FEV1:1960 cc-59%; VC-IN:2-260 cc-52%) alteration on diffusing capacity (TLCO 57%, 5%) and arterio-venous gasometry with hypoxæmia (PaO2 73 mm Hg) and increase of the alveolar-arterial O2 gradient (A-aO2 = 43) compatible with moderate lung fibrosis. A radiograph of the right hand showed small subcutaneous calcification in one digit. A barium swallow only showed reflux. Renal function was normal. Antinuclear antibodies were positive at a 1/400 titre with a nuclear pattern. Anticentromere and antiScI 70 antibodies were negative.

The patient was treated with nifedipine (30 mg/day) and prednisone (1 mg/kg a day initially with subsequent tapering). A few months later he complained of dyspnoea at rest, and clinical signs of right sided heart failure. PAP control by echocardiography (Doppler) had raised to 80 mm Hg. He died 12 months after diagnosis from cardio-respiratory failure. Renal function remained normal until his death. Necropsy was refused.

SS is a multisystem disorder characterised by an overproduction of collagen with involvement of the skin, blood vessels and visceral organs.

Over the past 25 years there have been increasing reports of environmentally induced SS. Organic solvents penetrate the skin, can be inhaled, and may produce metabolic changes in many organs, due both to a direct toxic effect and a possible immunogenetic susceptibility to SS.4-6 In most cases, avoiding exposure does not result in clinical improvement.1,7 Nevertheless, early diagnosis should be achieved. Raynaulds phenomenon is the first symptom in up to 70% of patients with SS.8 We suggest that a review of solvent exposure should include an anamnestic study and a normal check up of workers from relevant industries. In patients in whom Raynaulds phenomenon is present a complete physical examination, a nailfold capillaroscopy and a selective autoimmunity study (anticientromer and anti-ScI 70 antibodies) should be carried out,9 and further exposure avoided if positive.

Isospora bellii reactive arthritis in a patient with AIDS

Isospora bellii has been recognised as an opportunistic protozoan pathogen in patients with the acquired immunodeficiency syn- drome (AIDS).1 Parasitic infestation of the gastrointestinal tract has been previously reported as a possible cause of seronegative reactive arthritis.2 The common features were eosino- philia, asymmetric oligoarthritis affecting large joints of the lower limbs, and full improvement after elimination of the parasite.3 We report a case of reactive arthritis secondary to infection by I bellii in a patient with AIDS.

The patient, a 57 year old white woman, with human immunodeficiency virus (HIV) was infected by heterosexual transmission. In 1991, she started having diarrhea and migratory polyarthritis. Four months later she developed inflammatory arthritis affecting both hands and wrists, accompanied by morning stiffness.

A year before her admission her husband, who had been diagnosed with AIDS died of pneumocystis carinii pneumonia complications. On physical examination, she was puffy and coughed in the second, third and fourth metacarpophalangeal (MCP) joints in both hands. There were no aphthous ulcerations, skin rashes or evidence of conjunctivitis.

In laboratory tests, the erythrocyte sedimentation rate (ESR) of 38 mm/hour, a haemoglobin of 12.1 g/dl, a white blood cell (WBC) count of 5.6 x 10³/μl with an eosinophi- lic count of 0.56 x 10³/μl and platelets of 426 x 10³/μl. Blood chemistry and urinalysis findings were within normal limits. Results of the test for IgM rheumatoid factor, antinuclear antibody and HLA-B27 were negative. Anti-HIV antibody, performed by Western blot analysis. She had a CD4:CD8 ratio of 0.13 and an absolute CD4 count of 264 cells/mm³. Radiographs of the chest and in a follow-up after 6 months before the development of polyarthritis, were isolated from her stool samples an organism identified as Isospora bellii. The patient was treated with oral trimethoprim (160 mg) and sulphamethoxazole (800 mg), given four times daily for 10 days and then twice daily for three weeks and then diclofenac, 50 mg given three times a day. Three days later, her arthritis progressively improved and diarrhoea disappeared. Despite the improvement of her arthritis, arthritis did not recur. Unfortunately, this patient died in June 1993 due to AIDS.

Reactive arthritis has been reported in association with a number of enteric parasitic infections including Entamoeba histolytica and Cryptosporidium.6 Chronic enteric infec- tions with coccidial parasites have been associated with immunodeficient patients with Cryptosporidium and I bellii have been implicated as a cause of chronic diarrhea in patients with AIDS. Reactive arthritis has been reported in HIV-infected patients mainly in homosexual men.4 After parasite enteric infection has been described, sero- negative oligo- or polyarthritis asymmetric, additive or migratory with predominant involvement of joints of the lower limbs,5 but upper limb joints can be affected.

Our patient may have had reactive arthritis after enteric infection with I bellii. She developed symmetrical polyarthritis without cutaneous features of systemic rheumatic syndrome, involving both wrists and hands, accompanied by morning stiffness resembling rheumatoid arthritis.1 The diagnosis of parasite reactive arthritis is suggested by: eosinophilia, blood chemistry pattern, and the temporal sequence that this arthritis was triggered by I bellii infestation, and rheumatic manifestations, which improved after trimethoprim-sulphamethoxazole therapy. However, the mechanisms of reactive
arthritis involving *I. belli* and *Cryptosporidium* infestation in patients with AIDS are not yet well known. Further studies should help clarify these questions. We are not aware of any previous report of reactive arthritis after enteric infection due to *I. belli* and we believe this to be the first such report.

**AUTHORS’ REPLY** We are pleased that the first article in *Lessons of the Month* has attracted interest and correspondence.

In reply to Dr Edgar et al, we feel that the use of Bence-Jones protein (BJP) as a descriptive term for urinary monoclonal light chains is in such standard usage as to be fully acceptable; few clinicians or laboratory scientists would be in any doubt as to the meaning of this term.

The agarose gel electrophoretic assay used for the detection of urinary BJP in our laboratory has a sensitivity of 0-08 g/l, which after concentration of urine x200 gives a lower limit of detection of approximately 0-001 g/l of monoclonal BJP (Sheldon J, personal communication). In this case BJP was not quantitated but was expressed as two faint bands of kappa protein at initial testing. The laboratory routinely expresses BJP calculated as a percentage of total urinary protein.

It is our experience, and that of our colleagues in the laboratory, that the term ‘Bence-Jones’ can be applied to the presence of a monoclonal protein in persons with no evidence of myeloma, Waldenstoms macroglobulinemia, amyloidosis or other related B cell malignancy. We suggest that this term can only be applied once the condition is shown to be stable with time — five years for IgG and IgA and 10 years for IgM paraprotein. An alternative term monoclonal gammopathy of unknown significance (MGU) is better used when any doubt exists.

We agree with Dr Edgar et al, and hope that *Lessons of the month* highlights the need to follow up the findings of even a faint band of BJP with serial BJP measurements. It was this omission which led to the difficulties encountered in this case. However, we appreciate the concern expressed by Dr Edgar that early bone marrow examination be undertaken if any BJP is detected and there is general agreement that this decision should be based on clinical judgement. Most clinicians would find it impossible, for reasons of resource limitation and clinical acceptability, to perform bone marrow examination on every patient with any detectable BJP, although this is a moot point. Certainly levels of >0-01 mg/l are more suggestive of malignancy and should be investigated with bone marrow examination. As far as other investigations are concerned plain radiographs are generally regarded as a more sensitive indicator of the presence of myeloma. Isotope bone scans can often be normal in myeloma even with significant bony deposits. Interpretation of the finding of BJPs may be aided also by assay of β₂ microglobulin. β₂ microglobulin may be elevated either with deterioration in renal function or with myeloma tumour mass; interpretation of elevated levels may be difficult.

If *Lessons of the month* continues to draw attention to important clinical issues and to open areas of controversy then it will surely achieve its intended purpose.

Bence-Jones protein and vertebral osteoporosis

We welcome the introduction of *Lessons of the Month* and read with interest the case report submitted by Dr Hughes et al. regarding the investigation of patients presenting with back pain. As the authors rightly point out, the exclusion of occult lymphoproliferative disorders in this group of patients is of the utmost importance. There are, however, several points of concern arising from the case particularly in relation to the clinical interpretation of monoclonal urinary free light chains.

The use of the term Bence-Jones protein (BJP) can cause confusion as it refers to the original heating test for the detection of urinary monoclonal free light chains. These are now best detected using the more sensitive techniques of immunoelectrophoresis or immunofixation. As this interesting case demonstrates, serum immunoglobulin levels can remain normal in a few cases, even in the terminal stages of disease. It is therefore imperative that paired serum and urine samples are sent for immunochemical analysis.

We feel it is potentially misleading to say that ‘...Traces of urinary BJP in isolation can prove to be benign...’. It is generally agreed that their detection is highly suggestive of underlying lymphoproliferative disease in the majority of cases and it is wise to dismiss such findings as benign. In addition the definition of “a trace” will depend heavily on the detection system employed in individual laboratories — accurate quantitation of the free light chains should routinely be undertaken; measurement of total urinary protein is less informative. These are the important lessons we must learn from patients we occult myeloma, are to be detected and successfully treated.

We would emphasise that in patients presenting in this manner, a more aggressive investigational approach is indicated, including early bone marrow examination and radioisotope scanning of bone. Only when results from these investigations are available would it be advisable to monitor the patient the over time remembering that a repeat bone marrow examination is always an option at a later date.

**Antiphospholipid antibodies (aPL) in systemic lupus erythematosus. Are they specific tools for the diagnosis of aPL syndrome?**

We read with interest the paper by Ghirardello et al on antiphospholipid antibodies (aPL) in systemic lupus erythematosus (SLE) but would suggest that their conclusion, “lupus anticoagulant (LA) but not anticardiolipin antibody (aCL) positivity is a specific tool for the diagnosis of thrombotic complications...in SLE”, is interpreted with caution.

There are a number of methodological problems in setting up a study of this kind which should be highlighted:

1) This study was retrospective and it cannot be assumed that because aPL are present when aPL are present when the time of study, they were also aPL at the time of diagnosis of SLE. In fact, the authors do not specifically state in reference to the 47 patients who had experienced pregnancy, whether they were diagnosed as having SLE at that time. It is therefore likely that the recording of aPL complications using the...
Isospora belli reactive arthritis in a patient with AIDS.
