Antineutrophil cytoplasmic antibodies and the eosinophilia myalgia syndrome

The eosinophilia myalgia syndrome (EMS) is an inflammatory multisystem disease which emerged in epidemic form in 1989 and was linked to the ingestion of L-tryptophan.1 In the acute form of the EMS, severe myalgia and pronounced blood eosinophilia are accompanied by widespread organ involvement including the skin, lungs, serosal membranes, and the peripheral nervous system being involved most frequently.2,3 The chronic form of the EMS is characterised by progressive fascial and cutaneous fibrosis, leading to clinical pictures resembling eosinophilic fasciitis, accompanied bypolyneuropathy, chronic fatigue, and psychological dysfunction.4,5 A spectrum of vascular lesions has been detected including perivascular aggregation of mononuclear cells, intimal and medial thickening and fibrosis, ultrastructural alterations of the vascular endothelium, and frank vasculitis with mural infiltration by mononuclear cells.6 The last of these was found primarily in small arteries, veins and capillaries, and by immunofluorescence microscopy no deposition of immunoglobulins or complement components was found.7

These histopathological features resemble those of the pauci-immune small vessel vasculitides, a group of diseases strongly associated with antineutrophil cytoplasmic antibodies (pANCA).8 In the March 1991 issue of this journal Cilursu and colleagues8 reported a patient with acute EMS and perinuclear ANCA (pANCA) with anti-myeuroperoxidase (MPO) specificity together with a small vessel vasculitis in skeletal muscle. This report prompted the question whether EMS also is an ANCA associated disease. From a nationwide collection of EMS sera, we tested a random sample of 45 sera for ANCA. The sera were from 39 females (age 30–69 years) and six males (age 51–61 years) who fulfilled the diagnostic criteria of chronic EMS.4 ANCA testing was performed in compliance with the guidelines of the European ANCA Study Group with an indirect immunofluorescence test on ethanol fixed and formalin fixed granulocytes; antibody specificity was tested by specific enzyme linked immunosorbent assay (ELISA) using proteinase 3 (PR3), MPO, lactoferrin, lysozyme, elastase, and cathepsin G as antigens.5 For distinction between pANCA and antineutrophil antibodies (ANA), sera were also examined on cultured human cells.6

We found none of the 45 sera to be positive for ANCA. Likewise all sera were negative by ELISA testing for the above mentioned antibody specificities. A number of sera produced fluorescent staining on the alcohol fixed granulocytes; however, this was attributable to ANA. In a Chang cell assay, 19 of 45 sera (42%) tested positive for ANA.

The strongest clinical associations of ANCA have been shown to be that of anti-PR3 with Wegener’s granulomatosis (WG) and of anti-MPO with microscopic polyangiitis (MPA) and pauci-immune rapidly progressive glomerulonephritis (RPGN).9 These disorders have been categorised as the ANCA-associated vasculitides. In WG, 80% of patients are positive for cytoplasmic ANCA (cANCA); in generalised disease this is in the case in more than 90%, with anti-PR3 being the most frequent antibody sub specificity (table). The association between pANCA or anti-MPO and MPA or pauci-immune RPGN is less strong—approximately 65% of MPA patients are anti-MPO-positive. While anti-PR3 is highly specific for WG, anti-MPO has also been found at a low rate and at low titres in a number of other chronic inflammatory diseases.7

A strong association of ANCA with secondary vasculitis has not yet been found.9 However, these results thus add to the evidence that anti-PR3 and anti-MPO are important markers for the classification and clinical diagnosis of primary systemic vasculitides, but not secondary vasculitides. The low prevalence of ANCA in the EMS makes it unlikely that ANCA have a pathogenic role in this disorder.

Silent myocardial infarction in Wegener’s granulomatosis

At postmortem, patients with Wegener’s granulomatosis (WG) frequently show a clinically overlooked and diffuse disease process. Cardiologically, many such patients have been asymptomatic but present histological findings of specific heart involvement. We report two cases of silent myocardial infarction related to WG—a feature which, to our knowledge, has not been reported in clinical series.

Patient 1. A 42 year old man was admitted to hospital because of severe vasculitis flare. He had an eight month history of arthritis and lower limb dysesthesia. Examination showed an acutely ill patient with a 39°C fever. He had oral ulcers, haemorrhagic gingival hyperplasia, bilateral haemorrhagic nasal discharge with crusts, diffuse necrotic purpura and black discoloration of fingers and toes. Ankle jerks were absent. Standard blood tests showed: leucocyte count 9.6 × 10^{9/l}; serum creatinine 112 μmol/l; C reactive protein 278 mg/l; fibrin 12 g/l; total creatine kinase (CK) concentration 1102 U (normal range 5–0 100 U); cholesterol, triglyceride and blood glucose values were within the normal range. Microscopic haematuria was present at 15/HPF. The electrocardiogram showed ST segment elevation and loss of R waves in leads V1, V2, and V3. Silent anterior myocardial infarction was diagnosed and WG was suspected. It was confirmed by: a) anti-neutrophil cytoplasmic antibodies (diffuse cytoplasmic fluorescence) in the serum; b) panninutis demonstrated by computed tomodraphy scan; c) multineuritis on electro-physiological examination; d) necrotising vasculitis on skin biopsy. Lupus anti-coagulant and antidiolipin antibodies were absent. Antithrombin III, protein C and
protein S plasma concentrations were normal. Initial treatment comprised intravenous administration of methylprednisolone, cyclophosphamide and sodium heparinate. Other drugs included diltiazem, dinitrosothiobetaine, enalapril. The short term course was uneventful. At day 14, the patient had a sudden rupture of the spleen. Splenectomy was performed. Histological analysis of the spleen showed widespread necrotising vasculitis with haemorrhagic infarction. At day 30, coronaryography was normal. At month 24, the patient had no active sign of WG nor any recurrence of myocardial ischaemia.

**Patient 2.** A 41 year old woman was admitted for suspected systemic vasculitis. She had a two year history of chronic rhinitis with relapsing sinusitis and showed no productive cough with bloody sputum. A chest radiograph showed disseminated excavated pulmonary nodules. Fibroscopy disclosed a pseudotumoural aspect of the bronchial mucosa. Microscopic examination of a bronchial specimen showed giant cell granuloma. Treatment against tuberculosis was started with four drugs. Because distressing neurological signs appeared the patient was transferred to our department. Physical examination showed a febrile, disoriented, acutely ill woman with nasal obstruction, bilateral ear chondritis, diplopia, right upper eyelid ptosis, dysaesthesia and paralysis of the right arm and left plantar tend ankle jerk. Chest auscultation was normal. Standard blood tests showed: leucocyte count 16.7 x 10^9/l; creatinine 52 μmol/l; C reactive protein 252 mg/l; fibrin 10 g/l; total CK concentration 10/HPF. U with MB isoenzyme 179 U. Cholesterol, triglycerides and blood glucose values were within the normal range. Lowgrade haematuria was present at 10/HPF. The electrocardiogram showed ST segment and T wave elevation in leads V4 and V5, with loss of R waves in the anterior leads. Echocardiography showed septal akinesia and diffuse hypocontractility without dilatation of the left ventricle. Silent acute anterosetal myocardial infarction was diagnosed. A diagnosis of severe WG was further supported by: a) antineutrophil cytoplasmic antibodies (diffuse cytoplasmic fluorescence) in the serum; b) mononeuritis multiplex on electromyographic study; c) multiple bilateral infarts of the white matter on cerebral magnetic resonance imaging; d) typical granulomatous necrotising vasculitis on nasal biopsy. Tests for antiphospholipid antibodies were negative. Treatment included intravenous pulses of high-dose prednisolone followed by oral prednisone, monthly intravenous cyclophosphamide, and sodium heparinate. All symptoms remitted rapidly, except for mononeuritis multiplex that progressively deteriorated over a period of months. After eight cycles, cyclophosphamide was changed for daily oral etoposide which has been considered to be effective in neuropathy. At month 18, relapse of sinupusitis and pulmonary nodules required increased prednisone dosage and etoposide was stopped. At month 22, the patient had no active sign of WG nor any recurrence of myocardial ischaemia.

Because Wegener's granulomatosis was once a uniformly fatal disease, before successful use of cyclophosphamide therapy, early reports were only of postmortem findings. We reviewed 54 cases, found myocardial granulomata in six and focal coronaritis in 15; death was retrospectively attributed to myocardial infarction in two cases. A more recent comprehensive review reported the most common pathological findings as pericarditis in 50%, focal myocarditis in 25%, coronary arteritis in 50%, and myocardial infarction in 11% of WG postmortem cases in which the heart was examined.

Such high prevalence contrasts sharply with clinical data collected in the cyclophosphamide era. Only 10 (6%) of 158 WG patients had detectable heart involvement in the series reported by Hoffman et al. All had specific pericarditis and no myocardial ischaemia was reported. Heart involvement was not mentioned among the causes of death. In contrast, there have been several published reports of WG with myocardial involvement—heart muscle disease, heart block and supraventricular tachycardia, and cardiac mass.1-3

Our two patients had myocardial infarction clearly related to WG because: a) myocardial infarction was novel, with no angina in the past; b) myocardial infarction accompanied severe generalised WG flare, c) the extent of clinical systemic vasculitis was unusually diffuse (distal limb necrosis and splenic infarction in patient 1 and cerebral vasculitis in patient 2); d) atheroma could be rejected as the cause of myocardial infarction because of normal coronaryography in patient 1 and absence of any risk factor in patient 2; and e) no cardiac ischaemic event was observed during a two year follow up under immuno-suppressive therapy.

In the literature, we could find only two reports of myocardial infarction recognised in alive WG patients. Gatenby et al report the fulminating course of WG in a 28 year old man who died from painful and massive myocardial infarction. Pathological examination of the heart showed vasculitis with fibrinoid necrosis of the media and partial occlusion of the lumen by pale antemortem thrombus in all coronary vessels.6 In the other case reported in the literature, an embolic mechanism rather than vasculitis could account for the symptomatic myocardial ischaemia.7

Wegener's granulomatosis is defined as a small vessel vasculitis. The severity of the condition, and occasional associated death, might be related to the progression of vasculitis and thrombosis to larger sized vessels.8 Coronary wall inflammation and formation of luminal blood clot are two mutually non-exclusive processes that may have been responsible for myocardial ischaemia in our two patients.

In practical terms, cardiac enzymes and electrocardiography should be repeatedly monitored in a patient with WG flare.
Silent myocardial infarction in Wegener's granulomatosis.
