Effect of osteoprotegerin and osteoprotegerin ligand on osteoclast formation by arthroplasty membrane derived macrophages

I Itonaga, A Sabokbar, D W Murray, N A Athanasou

Abstract

**Objective**—Osteoprotegerin ligand (OPGL) is a newly discovered molecule, which is expressed by osteoblasts/bone stromal cells. This ligand and M-CSF are now known to be essential for osteoclast differentiation from marrow and circulating precursors. This study examined whether OPGL and its soluble receptor osteoprotegerin (OPG), influenced osteoclast formation from human arthroplasty derived macrophages, to determine if the effects of OPGL and OPG on these cells could contribute to the osteolysis of aseptic loosening.

**Methods**—OPG (± dexamethasone/M-CSF) was added to cultures of macrophages isolated from the pseudomembrane of loosened hip arthroplasties incubated on glass coverslips and dentine slices. OPG was added to cocultures of arthroplasty derived macrophages and UMR106 osteoblast-like cells. Osteoclast differentiation in long term cultures was assessed by expression of macrophage (CD14) and osteoclast markers (tartrate resistant acid phosphatase (TRAP), vitronectin receptor (VNR) and lacunar resorption).

**Results**—In the absence of osteoblastic cells, the addition of OPGL alone was sufficient to induce differentiation of macrophages (CD14+, TRAP+, VNR+) into TRAP+ and VNR+ multinucleated cells, capable of extensive lacunar resorption. OPG was found to inhibit osteoclast formation by arthroplasty macrophages in a dose-dependent manner. OPG (100 ng/ml) more than halved the formation of TRAP+ and VNR+ cells and the extent of lacunar resorption in co-cultures of UMR106 cells and arthroplasty macrophages.

**Conclusions**—This study has shown that macrophages, isolated from the pseudomembrane surrounding loose arthroplasty components, are capable of differentiating into osteoclastic bone resorbing cells and that OPG is required for this to occur. OPG inhibits this process, most probably by interrupting the cell-cell interaction between osteoblasts and mononuclear phagocyte osteoclast precursors present in the pseudomembrane.

(Arr Rheum Dis 2000;59:26–31)

Aseptic loosening is the commonest cause of late failure of cemented and uncemented joint replacements. Loosening of implant components is thought to occur in over 10% of cases within 20 years of the initial hip replacement. A heavy foreign body macrophage response to polymeric and metallic wear particle is found in the pseudocapsule and pseudomembrane surrounding the implant. Surrounding this macrophage rich infiltrate there is considerable periprosthetic osteolysis. The cellular mechanisms underlying this pathological bone resorption and the manner in which the heavy foreign body macrophage infiltrate in periprosthetic tissues contributes to this osteolysis remain uncertain.

Cells in the implant pseudoskin are known to produce humoral factors, including cytokines/growth factors and prostaglandins, which activate osteoblasts to stimulate osteoclastic bone resorption. Another means whereby macrophages contribute directly to the osteolysis of aseptic loosening is by differentiation of these cells into bone resorbing osteoclasts. It has been shown that mouse monocytes and tissue macrophages, including inflammatory foreign body macrophages derived from granulomas formed in response to subcutaneously implanted metallic and polymeric particles, are capable of differentiating into osteoclasts. Coculture with osteoblastic cells in the presence of 1,25 dihydroxyvitamin D3 is required for this to occur. We have also recently shown that human wear particle associated macrophages isolated directly from periprosthetic tissues surrounding loosened implants can differentiate into multinucleated cells showing all the functional and cytochemical characteristics of osteoclasts. In contrast with osteoclast formation from human monocyte and other inflammatory macrophage populations in vitro, which requires the addition of macrophage-colony stimulating factor (M-CSF) as well as 1,25(OH)2D3, arthroplasty macrophage-osteoclast differentiation does not require exogenous M-CSF. In the context of the heavy macrophage response to wear particles, macrophage-osteoclast differentiation may thus, represent an important cellular mechanism whereby osteolysis is effected in aseptic loosening in periprosthetic tissues.

Osteoclast differentiation from mononuclear phagocyte precursors is known to require the cooperation of osteoblasts/bone stromal cells. It has recently been shown that these cells express an osteoclast differentiation factor, also...
tered osteoprotegerin ligand (OPGL), which induces osteoclast formation from marrow and circulating precursors.\textsuperscript{16, 17} OPGL is a member of the tumour necrosis factor (TNF) ligand superfamily and interacts with an osteoclastogenesis inhibitory factor or osteoprotegerin (OPG), a secreted member of the TNF receptor family.\textsuperscript{18-20} In this study, we show that OPGL plays a major part in arthroplasty macrophage-osteoclast differentiation and that this process can be inhibited by OPG.

**Methods**

**MATERIALS**

For all incubations a minimal essential medium (MEM) (Gibco, UK) was supplemented with 100 IU/ml penicillin, 10 µg/ml streptomycin, 10 mM L-glutamine (Gibco, UK) and 10% fetal calf serum (FCS) (Gibco, UK) (MEM/FCS). Collagenase Type I, 0.25% trypsin solution and dexamethasone were purchased from Sigma Chemicals (UK). Recombinant human macrophage colony stimulating factor (M-CSF) was obtained from R & D Systems (UK). 1,25 dihydroxyvitamin D\textsubscript{3}, [1,25(OH)\textsubscript{2}]D\textsubscript{3} was purchased from Solvay Duphar (Netherlands). OPG and OPGL were kindly provided by Dr D Lacey, Amgen (Thousand Oaks, CA, USA). All incubations were carried out at 37°C in 5% CO\textsubscript{2}.

**ISOLATION OF CELLS FROM THE ARTHROPLASTY PSEUDOMEMBRANE**

Specimens of the femoral and acetabular pseudomembrane were obtained fresh from six patients (three women and three men; age range 48 to 85 years), undergoing revision arthroplasty for aseptic loosening of the hip who were initially diagnosed to be suffering from primary osteoarthritis. The cell suspension derived from these tissues was prepared as described previously.\textsuperscript{21} Briefly, tissue specimens were washed thoroughly with phosphate buffered saline (PBS) before being cut into small fragments and digested in MEM containing 1 mg/ml collagenase Type I for 30 minutes at 37°C; this was followed by a further one hour incubation in 0.25% trypsin. The digested tissue was filtered with a 70 µm cell strainer (Falcon, UK) and the filtrate centrifuged at 800 g for 10 minutes. The cell pellet was resuspended in MEM/FCS and the number of leucocytes determined in a haemocytometer after lysis of red blood cells using a 5% (v/v) acetic acid solution.

**CULTURE OF ARTHROPLASTY DERIVED MACROPHAGES: THE EFFECT OF OPG ON MACROPHAGE-OSTEOCLAST DIFFERENTIATION**

The effect of OPGL on macrophage-osteoclast differentiation was studied in four of the six specimens. The cell suspension obtained from arthroplasty tissues (1 x 10\textsuperscript{6} cells/well) was added to 96 well tissue culture plates containing 1 ml MEM/FCS, both in the presence and absence of one or more of the following factors: 30 ng/ml OPGL, 25 ng/ml M-CSF, and 10\textsuperscript{-8} M dexamethasone. These cultures were incubated for 1, 4, 7, 11 and 14 days and the culture medium containing these factors was replenished every three days. The extent of osteoclast formation was assessed in terms of the expression of cytochemical and functional markers of the osteoclast phenotype (see below).

**THE EFFECT OF OPG ON OSTEOCLAST FORMATION IN COCULTURES OF OSTEOBLASTS (UMR106 CELLS) AND ARTHROPLASTY DERIVED MACROPHAGES**

Osteoclast formation is known to occur when arthroplasty derived macrophages are cocultured with osteoblastic cells in the presence of 1,25(OH)\textsubscript{2}D\textsubscript{3}.\textsuperscript{14} The effect of OPG on osteoclast formation was assessed in this coculture system in five of the six specimens. Twenty four hours before the isolation of cells from arthroplasty tissues, 2 x 10\textsuperscript{5} rat osteoblastic UMR106 cells (kindly provided by Professor T J Martin, Melbourne, Australia)\textsuperscript{24} were added to 96 well tissue culture plates containing dentine slices and glass coverslips. The cell suspension obtained from arthroplasty tissues was added to each well (1 x 10\textsuperscript{5} cells/well) and incubated for two hours, after which time all dentine slices and coverslips were removed from the wells, washed vigorously in MEM/FCS to remove non-adherent cells, and then placed in 16 mm wells of a 24 well tissue culture plate containing 1 ml MEM/FCS supplemented with OPG (0, 10, 50, 100 ng/ml), 1,25(OH)\textsubscript{2}D\textsubscript{3} (10\textsuperscript{-7} M) and dexamethasone (10\textsuperscript{-8} M). These cocultures were incubated for 1, 7 and 14 days and the culture medium containing these factors was replenished every three days. The extent of osteoclast formation was assessed in terms of the expression of cytochemical and functional markers of the osteoclast phenotype (see below).

**CYTOCHEMICAL CHARACTERISATION OF CULTURED CELLS**

After 1, 4, 7, 11 and 14 days incubation, cell cultures on coverslips (incubated both in the presence and absence of UMR106 cells) were characterised histochemically for the expression of tartrate resistant acid phosphatase (TRAP)\textsuperscript{25} using a commercially available kit (Sigma, UK). Cell cultures on coverslips were also stained immunohistochemically by an indirect immunoperoxidase technique\textsuperscript{3} with the monoclonal antibodies 23C6 (a gift of Professor M A Horton, London, UK)\textsuperscript{24} and GRS1;\textsuperscript{26} these antibodies are directed respectively against CD51, the vitronectin receptor (VNR), an osteoclast associated antigen, and CD14, a macrophage associated antigen that is not expressed by osteoclasts.\textsuperscript{26}
This provides a smooth surfaced mineralised substrate for the assessment of lacunar resorption. After cells had been cultured on dentine slices for 1, 4, 7, 11 and 14 days, the slices were removed from the wells, rinsed in PBS, and placed in 0.25% trypsin for 15 minutes; dentine slices were then washed vigorously in distilled water and left overnight in 0.25 M ammonium hydroxide. In this way all cells are completely removed from the dentine slice, permitting examination of the dentine surface for evidence of lacunar resorption. The slices were then washed in distilled water, stained with 0.5% (w/v) toluidine blue, and examined by light microscopy.

The extent of lacunar resorption on dentine slices was determined by counting the number of resorption pits. Each experiment was repeated at least three times and for each treatment the data were expressed as the mean number of lacunar pits formed on three dentine slices. The effect of adding mediators was quantified by calculating the percentage change in the mean number of pits. Statistical significance of the effect of OPG and OPGL on lacunar resorption changes was assessed using Student’s t test.

Results

OPGL Studies

Effect of OPGL on arthroplasty macrophage-osteoclast differentiation

Adherent cells isolated from the arthroplasty pseudomembrane, incubated for 24 hours on glass coverslips, both in the presence and absence of 30 ng/ml OPGL, showed strong expression of CD14, a macrophage cell surface antigen that is known not to be present on osteoclasts. These cells were largely negative for the osteoclast markers, TRAP and VNR. Lacunar resorption was not seen in 24 hour cultures on dentine slices.

After 14 days incubation, the addition of 30 ng/ml OPGL to arthroplasty macrophage cultures was found to be sufficient to induce macrophage-osteoclast differentiation in the absence of osteoblastic cells and human M-CSF. In the presence of 30 ng/ml OPGL alone, many TRAP+ and VNR+ mononuclear and multinucleated cells were observed on the coverslips, and numerous lacunar resorption pits were found on the dentine slices (fig 1). The mean number of pits on each dentine slice was 32. In the absence of OPGL, pits were not formed on dentine slices. Macrophage cell cultures incubated for 14 days in the presence of OPGL and M-CSF, or OPGL and dexamethasone, showed a small but not significant increase in the number of resorption pits formed on dentine slices compared with cell cultures incubated with OPGL alone. However, when OPGL, M-CSF and dexamethasone were added together to cell cultures, there was a marked increase (70%) in the extent of lacunar resorption compared with cultures incubated with OPGL alone (p=0.025) (fig 2).

The time course of arthroplasty macrophage-osteoclast differentiation in the presence of OPGL

As noted above, 24 hours cultures on glass coverslips and dentine slices in the presence of OPGL (30 ng/ml), both in the presence and absence of 25 ng/ml M-CSF and 10−5 M dexamethasone, were negative for TRAP and
compared with control cultures—that is, in the absence of OPG. Cultures with no added OPG). (Bars represent mean (SD)). *p<0.05, **p<0.001 as compared with control cultures (that is, cocultures in response to various concentrations of OPG after 14 days incubation. Results represent pit numbers expressed as percentage of values obtained in control cultures (table 1)). Arthroplasty macrophage cultures, incubated in the presence of OPGL and M-CSF and/or dexamethasone, showed a similar pattern of osteoclast differentiation. In these conditions, a few TRAP+ and VNR+ cells and resorption pits were found after four days incubation and numerous large lacunar resorption pits were seen after incubation for 14 days, both in the presence and absence of dexamethasone (table 1).

**OPG STUDIES**

**Arthroplasty macrophage-osteoclast differentiation in coculture with UMR106 cells**

Arthroplasty macrophage-osteoclast differentiation was seen in cocultures of arthroplasty derived macrophages and UMR106 cells. In all cases, 24 hour cocultures of arthroplasty macrophages and UMR106 cells on glass coverslips in the presence of 1,25(OH)2D3 and dexamethasone, were largely positive for the macrophage marker, CD14, and almost entirely negative for the osteoclast markers, TRAP and VNR. In one case, a few isolated TRAP+ and VNR+ multinucleated cells were seen in 24 hour cultures on coverslips and single resorption pits were seen in the corresponding cultures on dentine slices. This was presumably because of the presence of osteoclasts in the cell suspension isolated from the arthroplasty membrane. In all cases studied, no pits were formed in the absence of UMR106 cells after 24 hour incubation.

After seven days incubation, cocultures of arthroplasty macrophages and UMR106 cells, incubated in the presence of 1,25(OH)2D3 and dexamethasone on coverslips, contained numerous TRAP+ and VNR+ mononuclear and multinucleated cells. In 14 day cocultures of arthroplasty macrophage and UMR106 cells, incubated in the presence of 1,25(OH)2D3 and dexamethasone, extensive lacunar pit formation was evident on all dentine slices.

**OPG inhibition of arthroplasty macrophage-osteoclast differentiation in coculture with UMR106 cells**

The addition of OPG to cocultures of arthroplasty macrophages and UMR106 cells, incubated in the presence of 1,25(OH)2D3 and dexamethasone, resulted in a dose dependent inhibition of macrophage-osteoclast differentiation and lacunar resorption (fig 3). In seven day cultures on coverslips, the number of TRAP+ and VNR+ mononuclear and multinucleated cells was decreased. In 14 day cocultures of arthroplasty macrophages and UMR106 cells on dentine slices, the number of lacunar resorption pits formed was also inhibited dose dependently. Relative to untreated controls, the addition of 10, 50, and 100 ng/ml of OPG resulted in inhibition of pit formation by 23% (p=0.021), 41% (p=0.014) and 57% (p=0.004), respectively.

**Discussion**

Wear particles derived from implant biomaterials induce a pronounced foreign body macrophage response in both the pseudocapsule and pseudomembrane surrounding arthroplasty.
components. The clinical severity and rapidly of onset of aseptic loosening can be correlated with both the amount of wear particle deposition and the extent of the macrophage response in these periprosthetic tissues. In this study we have shown that the capacity of arthroplasty macrophages to differentiate into osteoclasts is OPGL dependent and that this process is inhibited by OPG in a dose dependent fashion.

Our results show that the inflammatory foreign body macrophage infiltrate in periprosthetic tissues, surrounding loose arthroplasty components, contains mononuclear osteoclast precursors and that these cells express the phenotypic characteristics of macrophages and not osteoclasts. Post-mitotic osteoclast precursors of marrow origin have been shown to lose and to acquire macrophage and osteoclast markers respectively, in the process of osteoclast differentiation. This is paralleled by changes in the cytochemical and functional phenotype that occur in our culture system where isolated arthroplasty derived cells exhibit macrophage and not osteoclast characteristics; becoming TRAP* and VNR* and acquiring the ability to carry out extensive lacunar resorption after OPGL administration or when cocultured with osteoblasts.

OPGL is a membrane expressed ligand first identified on T cells. It is a novel member of the TNF ligand superfamily. The same ligand has been identified on osteoblasts and bone marrow stromal cells and with M-CSF has been shown to induce the differentiation of osteoclasts from circulating and marrow precursors. It has been shown for some time that in monocyte and macrophage populations there are mononuclear osteoclast precursors that, when cultured with osteoblastic cells, in the presence of M-CSF and calcitropic hormones such as 1,25(OH)2D3, are capable of differentiating into osteoclasts in vitro. Osteoclast precursors isolated from periprosthetic tissues form a unique category of such mononuclear phagocyte precursors in that they do not require the addition of exogenous M-CSF for osteoclast formation.

In this study, we have shown that OPGL can substitute for osteoblasts and 1,25(OH)2D3 in promoting macrophage-osteoclast differentiation and that indeed OPGL is the sole exogenous humoral factor that is required for this to occur. These findings indicate that the mononuclear phagocyte osteoclast precursors in the macrophage infiltrate of the arthroplasty membrane must express a receptor for OPGL. Two receptors for OPGL have recently been identified: the first is soluble decoy receptor—that is, OPG—and the other is a membrane bound receptor, known as OPGL-R. OPGL-R protein expression has been reported on activated T lymphocytes, dendritic cells, osteoclast precursors and mature osteoclasts. Haynes et al have recently shown that the expression of mRNA for OPGL and OPGL-R is stimulated by human mononuclear cells exposed to orthopaedic biomaterials such as titanium.

OPG inhibition of arthroplasty macrophage-osteoclast differentiation accords with a central role for OPGL in inducing osteoclast formation and bone resorption in aseptic loosening. OPG is a novel member of the TNF receptor superfamily, which, in contrast with other TNF receptors, lacks a transmembrane domain. This indicates that OPG is secreted as a soluble factor that may act to modulate osteoclast formation in an autocrine or paracrine fashion. OPG is produced by human and mouse osteoblasts and has been shown to bind to stromal cells that support osteoclast differentiation. Both in vivo and in vitro studies, have shown that OPG has a major effect on bone resorption. Transgenic mice expressing OPG cDNA have high circulating levels of OPG and are osteopetrotic, exhibiting decreased number of osteoclasts in bone, whereas OPG deficient mice are osteoporotic. As we have shown that OPGL and OPG profoundly influence osteoclast formation from mononuclear phagocyte osteoclast precursors isolated directly from the arthroplasty pseudomembrane, these factors are likely to play a major part in controlling the osteolysis of aseptic loosening. Osteoclast formation in periprosthetic tissues can be viewed as a balance between the production of OPGL and OPG, its soluble decoy receptor, by stromal cells and inflammatory cells at the bone and implant interface.

Of interest in regard to osteoclast formation and bone resorption in aseptic loosening is the role of various cellular and humoral factors on OPG and OPGL production. Inflammatory cells such as T cells are present in the arthroplasty membrane and may influence osteoclast differentiation and periprosthetic osteolysis by modulating OPGL expression and OPG production. Of the cytokines known to be abundant in periprosthetic tissues in aseptic loosening, interleukin 1 and TNF, but not interleukin 6, have been shown to increase OPG mRNA expression by osteoblasts. Thus, interleukin 1 and TNF, which are both known to stimulate the bone resorbing activity of osteoclasts, would appear to act conversely to downregulate osteoclast formation. PGE2, which is also abundant in periprosthetic tissues, has been shown to increase OPGL production and to decrease OPG release, thus stimulating osteoclast formation and bone resorption. Macrophages are also capable of producing 1,25(OH)2D3, the active metabolite of vitamin D. This has been shown to increase the ratio of OPGL to OPG production and thus osteoclast formation. In the heavy foreign body macrophage infiltrate in periprosthetic tissues, increased local production of 1,25(OH)2D3 by these cells may be another mechanism whereby osteoclast formation and osteolysis is increased.

The authors wish to thank Dr D Lacey, Amgen, CA for providing the OPG and OPGL... Funding: this research was funded by the Wellcome Trust.

Effect of osteoprotegerin and osteoprotegerin ligand on osteoclast formation

Effect of osteoprotegerin and osteoprotegerin ligand on osteoclast formation by arthroplasty membrane derived macrophages
