Role of RANKL and RANK in bone loss and arthritis

D Holstead Jones, Y-Y Kong, J M Penninger

The tumour necrosis factor family molecule RANKL (RANKL, TRANCE, ODF) and its receptor RANK are key regulators of bone remodelling and regulate T cell/dendritic cell communications, and lymph node formation. Moreover, RANKL and RANK are expressed in mammary gland epithelial cells and control the development of a lactating mammary gland during pregnancy and the propagation of mammalian species. Importantly, RANKL and RANK are essential for the development and activation of osteoclasts and bone loss in response to virtually all triggers tested. Therapeutically, inhibition of RANKL function via the decoy receptor osteoprotegerin completely prevents bone loss at inflammed joints and has partially beneficial effects on cartilage destruction in all arthritis models studied. Modulation of these systems provides a unique opportunity to design novel treatments to inhibit bone loss and crippling in arthritis.

Morphogenesis and remodelling of bone entail the synthesis of bone matrix by osteoblasts and the coordinate resorption of bone by osteoclasts. It has been estimated that about 10% of the total bone mass in humans is being remodelled each year. Osteoblasts and osteoclasts arise from distinct cell lineages and maturation processes—that is, osteoclasts arise from mesenchymal stem cells while osteoclasts differentiate from haematopoietic monocyte/macrophage precursors. Imbalances between osteoclast and osteoblast activities can arise from a wide variety of hormonal changes or perturbations of inflammatory and growth factors, resulting in skeletal abnormalities characterised by decreased (osteoporosis) or increased (osteopetrosis) bone mass.

Increased osteoclast activity is seen in many osteopenic disorders, including postmenopausal osteoporosis, Paget’s disease, lytic bone metastases, or rheumatoid arthritis, leading to increased bone resorption and crippling bone damage. Various factors have been described that are both bone resorptive factors, or rheumatoid arthritis, leading to increased bone resorption and crippling bone damage. Various factors have been described including CSF1 (MCSF), IL1, TGFβ, TGFα, TNFα, TNFβ, IL6, vitamin 1,25-hydroxyvitamin D3, IL11, calcitonin, PGE2, or parathyroid hormone (PTH) that affect osteoclastogenesis at distinct stages of development. However, genetic ablation experiments have shown that these factors are not essential for osteoclast development in vivo. Because of the enormous social and economic impacts of bone loss and crippling to human welfare and the search to increase human life span without the “side effects” of old age, it was of paramount importance to identify essential factors involved in osteoclast development and bone remodelling. The essential molecules have been recently identified to be the TNF-TNFR superfamily proteins RANKL, RANK, and OPG.

The TNF family molecule RANKL (receptor activator of NFκB ligand; also known as osteoprotegerin ligand [RANKL]; TNF related activation induced cytokine [TRANCE], osteoclast differentiation factor [ODF], and TNFSF11) and its receptor RANK (TNFRSF11A) are key regulators of bone remodelling and essential for the development and activation of osteoclasts. RANKL also regulates T cell/dendritic cell communications, dendritic cell survival, and lymph node organogenesis. Moreover, production of RANKL by activated T cells directly controls osteoclastogenesis and bone remodelling and explains why autoimmune diseases, cancers, leukemias, asthma, chronic viral infections, and periodontal disease result in systemic and local bone loss. In particular, RANKL seems to be the pathogenetic principle that causes bone and cartilage destruction in arthritis. Inhibition of RANKL function via the natural decoy receptor osteoprotegerin (OPG, TNFRSF11B) prevents bone loss in postmenopausal osteoporosis and cancer metastases and completely blocks bone loss and crippling in various rodent models of arthritis. Intriguingly, RANKL and RANK play essential parts in the formation of a lactating mammary gland in pregnancy. This system provided a novel and unexpected molecular paradigm that links bone morphogenesis, T cell activation and the organisation of lymphoid tissues, and mammary gland formation required for the survival of mammalian species. Inhibition of RANKL function via its natural decoy receptor OPG or small molecules might be the future treatment of choice to abolish osteoporosis, tooth loss, or crippling in arthritis.

RANKL

RANKL/OPGL/TRANCE/ODF/TNFSF11 was cloned simultaneously by four independent groups. The rankl gene encodes a TNF superfamily molecule of 316 amino acids (38 kDa) and three RANKL subunits assemble to form the functional trimeric molecule. Trimeric RANKL is made as a membrane anchored molecule and can then be released from the cell surface as a soluble homotrimeric molecules after proteolytic cleavage by the metalloprotease disintegrin TNFα convertase (TACE). It remains to be seen whether TACE is indeed the critical protease required for the release of RANKL from the cell surface. Although it has been proposed that soluble and membrane bound RANKL might have different biological functions, for example, membrane bound RANKL might work more efficiently than soluble RANKL, both soluble and membrane bound RANKL can function as potent agonistic ligands for osteoclastogenesis in vitro. The potential differences between soluble and membrane bound RANKL should be investigated further.

RANKL is highly expressed in osteoblast/stromal cells, primitive mesenchymal cells surrounding the cartilaginous anlagen and hypertrophying chondrocytes. RANKL mRNA has also been observed in prehypotrophic and hypertrophic chondrocytes at day 15 of embryogenesis and extraskeletal tissues such as the brain, heart, kidneys, skeletal muscle, and skin throughout mouse development. RANKL expression can be upregulated by bone resorbing factors such as glucocorticoids, vitamin D3, IL1, IL6, IL11, IL17, TNFα, PGE2...

Abbreviations: TNF, tumour necrosis factor; RANKL, receptor activator of NFκB ligand; OPG, osteoprotegerin; TACE, TNFα convertase; ODF, osteoclast differentiation factor; TRANCE, TNF related activation induced cytokine; TRAF, tumour necrosis factor receptor associated factor; RA, rheumatoid arthritis
or PTH.\textsuperscript{4,13} Using in vitro culture systems, RANKL can both activate mature osteoclasts and mediate osteoclastogenesis in the presence of CSF1.\textsuperscript{4} As it was unclear whether RANKL was indeed essential for osteoclast development and function in vivo, our group created the first rankl mutant mice using gene targeting.\textsuperscript{4} Rankl\textsuperscript{-/-} mice display severe osteopetrosis, stunted growth, and a defect in tooth eruption, and rankl\textsuperscript{-/-} osteoblasts cannot support osteoclastogenesis. These mice still contain haematopoietic precursors that can differentiate into phenotypically and functionally mature osteoclasts in vitro in the presence of recombinant RANK and CSF1\textsuperscript{14} and in vivo after injection of recombinant RANKL (JMP, unpublished data). Importantly, osteoblast cell lines derived from rankl\textsuperscript{-/-} mice do not support osteoclast formation indicating that the defect in osteoclastogenesis observed in rankl\textsuperscript{-/-} mice is attributable to an intrinsic defect in osteoblastic stroma.

Whereas csf1 mutant op/op mice display a developmental arrest in both monocyte/macrophage and osteoclast lineages, rankl\textsuperscript{-/-} mice display normal monocyte/macrophage differentiation and normal differentiation of dendritic cells.\textsuperscript{1} The osteoclast defect in csf-1 mutant op/op mice is not absolute and older op/op mice do have, albeit only few osteoclasts. Moreover, the defect in op/op mice can be reversed by transgenic overexpression of Bcl-2 in the osteoclast/macrophage lineage indicating that—in contrast with RANKL—CSF1 expression is not essential for osteoclast development.\textsuperscript{4} Whether Bcl-2 overexpression would also rescue the phenotype in rankl\textsuperscript{-/-} mice needs to be explored. Thus, our genetic data provided the first proof that RANKL is a specific and essential differentiation factor for osteoclast precursors. Moreover RANKL is an essential activation factor for mature osteoclasts (fig 1).

**RECEPTOR ACTIVATOR OF NFκB LIGAND—RANK**

The receptor for RANKL is RANK (receptor activator of NFκB also known as TRANCE-R, ODAR, or TNFRSF11A). RANK is a member of TNF-R superfamily, expressed as a transmembrane heterotrimer on the surface of haematopoietic osteoclasts progenitors, mature osteoclasts, chondrocytes, mammary gland epithelial cells,\textsuperscript{14,15} trophoblast cells, and multiple epithelial tumour cell lines (JMP, unpublished data). In vitro ligation of RANK with RANKL results in osteoclastogenesis from progenitor cells and the activation of mature osteoclasts.\textsuperscript{4,16} Mice with a genetic mutation of RANK are phenocopies of rankl\textsuperscript{-/-} mice and have a complete block in osteoclast development that can be restored by reintroduction of RANK into bone marrow progenitor cells.\textsuperscript{17} The osteopetrosis observed in these mice can be reversed by transplantation of bone marrow from rank\textsuperscript{+/-} mice, indicating that rank\textsuperscript{+/-} mice have an intrinsic defect in osteoclast function.\textsuperscript{18} Thus, the interaction between RANKL expressed by stromal cells/osteoblasts and its receptor RANK expressed on osteoclast precursors are essential for osteoclastogenesis (fig 1). Importantly, in human familial expansile osteolysis, a rare autosomal dominant bone disorder characterised by focal areas of increased bone remodelling,\textsuperscript{19} a heterozygous insertion mutation in exon 1 of RANK has been noted that appears to increase RANK mediated NFκB activation and thus might be causal for the disease. All biochemical, functional, and genetic results in humans and mutant mice established the absolute dependency of osteoclast differentiation and activation of mature osteoclasts on the expression of RANKL and RANK.

When RANK on osteoclasts is activated it sends signals into the cells through adapter proteins (fig 2). RANK contains 383 amino acids in its intracellular domain (residues 234–616), which contain three putative binding domains (termed I, II, and III) for tumour necrosis factor receptor associated factors (TRAFs).\textsuperscript{20} Mapping of the structural requirements for TRAF/RANK interaction revealed multiple TRAF binding sites clustered in two distinct domains in the RANK cytoplasmic tail. These TRAF binding domains were shown to be functionally important for the RANK dependent induction of NFκB and c-Jun NH2-terminal kinase (JNK) activities. In particular, TRAF6 interacts with membrane proximal determinants distinct from those binding TRAFs 1, 2, 3, and 5. When this membrane proximal TRAF6 interaction domain was deleted, RANK mediated NFκB signalling was completely inhibited while JNK activation was only partially inhibited\textsuperscript{21–24} suggesting that interaction with TRAFs is necessary for NFκB.

![Diagram of RANKL and RANK signaling](https://example.com/diagram.png)
TRAP mutant mice develop calcification of their large arteries whereas NFκB1/NFkB2 double mutant mice completely lack TRAP osteoclasts. Thus, TRAF6 is a critical factor involved in the activation of mature osteoclasts but other TRAFs (and possibly other molecules) seem to be able to partially substitute for the loss of TRAF6 during osteoclast development. In line with these data, osteoclastogenesis can be initiated in rank−/− mice by transfer of mutant RANK that lacks the TRAF6 binding site.

RANKL also activates the anti-apoptotic serine/threonine kinase Akt/PKB through a signalling complex involving c-Src and TRAF6. c-Src and TRAF6 interact with each other and with RANK after receptor engagement and a deficiency in c-Src or addition of Src family kinase inhibitors blocks TRANCE mediated Akt/PKB activation in osteoclasts. TRAF6, in turn, increases the kinase activity of c-Src leading to tyrosine phosphorylation of downstream signalling molecules such as c-Cbl. Moreover, RANK can recruit TRAF6, Cbl family scaffolding proteins, and the phospholipid kinase PI3-K in a ligand and Src dependent manner. RANKL mediated Akt/PKB activation is defective in cbl−/− dendritic cells. These findings implicate Cbl family proteins as not only negative regulators of signalling, but also as positive modulators of tyrosine phosphorylation of downstream signalling molecules.

Expression of OPG in ST2 stromal cell line and human bone marrow stromal cells is downregulated by bone resorbing factors such as vitamin D3 [1,25(OH)2D3], prostaglandin E2 (PGE2), or, glucocorticoids and upregulated by Ca+ ions and TGFβ. OPG is also expressed in follicular dendritic cells (identified as FDCR-1) and is upregulated after CD40 stimulation. In addition to osteoporosis, some but not all OPG mutant mice develop calcification of their large arteries and RANKL and RANK transcripts are detected in the calcified arteries of OPG mice. Transgenic OPG delivered from modified RANKL transgenic mice blocks bone loss in osteoporotic female rats. Thus, OPG and/or modulation of RANKL–RANK signalling pathway may play an important part in both pathological and physiological calcification processes. Such findings may also explain the observed high clinical incidence of vascular calcification in the osteoporotic patient population. As woman with osteoporosis have increased incidence of strokes, OPG, RANKL, and RANK might play, similar to the CD40 and CD40L system, a part in the pathogenesis of atherosclerosis, strokes, or heart attacks via a yet unknown effect on blood vessels.

OLEOSTROPROTEGERIN

Osteoprotegerin (OPG, “protector of the bone”; also known as osteoclastogenesis inhibitory factor, OCIF) is a secreted protein with homology to members of the TNF receptor family. The OPG gene encodes a 44 kDa protein that is post-translationally modified to a 55 kDa molecule through N-linked glycosylation. Although OPG is a member of the TNF receptor family, which normally form trimers, OPG is secreted as a soluble dimer. OPG functions as a soluble decoy receptor to RANKL and competes with RANK for RANKL binding. Consequently, OPG is an effective inhibitor of osteoclast maturation and osteoclasts activation in vitro and in vivo. High systemic levels of OPG in OPG transgenic mice cause osteoporosis with normal tooth eruption and bone elongation and inhibit the development and activity of endosteal, but not periosteal, osteoclasts. As expected, OPG deficient mice display severe osteoporosis associated with a high incidence of fractures, indicating that the level of bone mass correlates with the levels of OPG in mice. Expression of OPG in ST2 stromal cell line and human bone marrow stromal cells is downregulated by bone resorbing factors such as vitamin D3 [1,25(OH)2D3], prostaglandin E2 (PGE2), or, glucocorticoids and upregulated by Ca+ ions and TGFβ.

ROLE OF RANKL AND RANK IN THE IMMUNE SYSTEM

At around the same time when we had the first evidence that RANKL might play a part in osteoclast development, RANKL (TRANCE) was independently cloned by two other groups as a molecule expressed on the surface of activated T cells. Both soluble and membrane-bound RANKL is produced by activated CD4+ and CD8+ T cells. The RANKL is also expressed in lymph nodes, spleen, thymus and intestinal lymphoid patches, and immature CD4+CD8+ thymocytes. Osteoclastogenesis...
expression in T cells is induced by antigen receptor engagement and is regulated by calcineurin, ERK1/ERK-2, and PKC regulated signalling pathways.14 RANK is expressed on the surface of dendritic cells and mediates their maturation.20 Proliferative precursors and RANKL-RANK interactions can induce cluster formation, Bcl-XL expression, survival, CD40 expression, and IL12 production in dendritic cells.7,9 In contrast with CD40L/CD40, RANKL-RANK signalling does not change the expression of cell surface molecules such as MHC class II, CD80, CD86, and CD54. Whereas CD40L is primarily expressed on activated CD4+ T cells, RANKL is expressed on both activated CD4+ and CD8+ T cells.9,14 Moreover, the maximal level of RANKL after the initial T cell activation event is 48 hours and high levels of RANKL expression are sustained until 96 hours, while CD40L is rapidly expressed and downregulated.20 Thus, CD40L-CD40 interactions might primarily control the initial priming stage whereas RANKL-RANK might act at later time points than CD40L during the immune response.

OPG was found in a screen to identify novel genes expressed in follicular dendritic cells and OPG can be found on the cell surface of DCs probably by capturing of soluble OPG to the cell membrane via binding of a hyaluronic acid binding region present in OPG.8 Thus, like the interactions between CD40-L and CD40, or CD28 and CD80/CD86, it has been suggested that RANKL-RANK might regulate dendritic cell functions, T cell activation, and T cell-dendritic cell communication in vitro.15 Based on these studies, various groups are currently trying to control the dendritic cell fate via RANKL-RANK and OPG to modulate in vivo dendritic cell survival and to enhance the efficiency of dendritic cell based vaccinations for anti-tumour therapy or the treatment of autoimmune diseases. Moreover, at least in theory it is also possibly that OPG might modulate this interaction.

It has been shown that treatment of antigen pulsed mature dendritic cells with soluble RANKL in vitro increases the number and persistence of antigen presenting dendritic cells in the draining LN in vivo.16 Furthermore, RANKL treatment increased antigen specific primary T cell responses. Interestingly, significant memory responses were observed only in mice injected with RANKL treated dendritic cells.16 Although the mechanisms are not clear, these increased primary and memory T cells responses after vaccination with RANKL treated dendritic cells could be contributory to increased altered cytokine production such as expression IL12 and/or increased number of antigen pulsed dendritic cells. Moreover, it has been suggested that CD40L/CD40 interactions regulate T/B responses whereas RANKL/RANK might have a role in memory T cell responses.18 However, whereas CD40L is essential for the T cell dependent B cell responses such as germinal centre formation, affinity maturation and class switching,19 germinatal centre formation, Ig class switching and the production of neutralising antiviral Abs are not overtly affected in rankl-/- mice and all the B cell defects of these mutant could be explained by the absence of lymph nodes (Young-Yun Kong and J M Penninger, unpublished data). In the final analyses of all the published genetic and functional studies on RANKL, RANK, and OPG, it seems that although these molecules can influence some aspects of lymphocyte and dendritic cell functions, none of these molecules plays an essential function in T cell-RANKL interaction that cannot be compensated for by other molecules such as CD40L/CD40. Thus, the essential and true function of RANKL/RANK in the immune system and communication between dendritic cells and T cells needs to be elucidated. For example, as expression of these molecules can be controlled by sex hormones,14,16 we speculate that this system might control sex specific differences in immunity and could be involved in the higher incidence of autoimmune diseases like arthritis in women and/or the often observed improvement of rheumatoid arthritis during pregnancy.

During the initial analyses of our rankl-/- and later rank-/- mutant mice, a completely unexpected immunological phenotype became evident: rankl-/- and rank-/- mice lack all lymph nodes but display intact splenic architecture and develop Peyer’s patches normally, suggesting that RANKL and RANK have a specific and essential role in lymph node organogenesis.13,15 Defective lymph node development in rankl-/- mice correlates with a significant reduction in lymphotixin LTαβ and CD4+CD8αβ cells and their failure to form clusters in the rudimentary mesenteric lymph node anlage.27 Transgenic RANKL mediated restoration of lymph node development required LTαβ expression on CD4+CD4+CD3+ and CD3+CD19+ cells as lymph node formation could not be induced in LTαβ mice. The authors proposed that both RANKL and LTαβ regulate the colonisation and cluster formation by CD45+CD4+CD3+ cells during lymph node organogenesis.27 Importantly, RANKL disruption provided the first evidence that development of lymph nodes and Peyer’s node patches can be genetically uncoupled. The exact cellular and molecular mechanism of RANKL-RANK regulated lymph node morphogenesis needs to be established.

T CELLS AND BONE: OSTEOIMMUNOLOGY

Bone remodelling and bone loss is controlled by a balance between RANKL/RANK and the RANKL decoy receptor OPG. As RANKL is made by T cells after antigen-receptor stimulation, we asked the question whether T cell derived RANKL can indeed regulate the development and activation of osteoclasts—that is, whether activated T cells can modulate bone turnover via RANKL. In an in vitro cell culture system, activated T cells can directly trigger osteoclastogenesis via RANKL. Importantly, systemic activation of T cells in vivo leads to a RANKL dependent increase in osteoclastogenesis followed by bone loss. All in vitro and in vivo effects of T cells on osteoclasts could be blocked by the administration of the decoy receptor OPG.3 In a recent study it has been confirmed that transgenic overexpression of RANKL in T cells restores osteoclastogenesis in a rankl+ background and partially restores normal bone marrow cavities.19 These data showed that systemic activation of T cells leads to bone loss, indicating that, through their production of RANKL, T cells are crucial mediators of bone loss in vivo. The results also provided a novel paradigm for T cells as regulators of bone physiology.

As mutant mice that lack T cells still have normal bone cavities and tooth eruption, T cells are probably not required for normal bone homeostasis. However, chronic systemic T cell activation such as in autoimmune diseases or viral infections or local inflammation within the bone attributable to metastasis, infections, bone implants such as artificial hips, and fractures, or joint inflammation in arthritis probably mediates of bone loss in vivo. The results also provided a novel paradigm for T cells as regulators of bone physiology.

These findings provide a molecular explanation for bone loss associated with diseases having immune system involvement, such as adult and childhood leukaemias, cancer metastasis, autoimmunity, and various viral infections. Inhibition of RANKL function via OPG or a related molecule might therefore prevent bone destruction in multiple diseases. Moreover, it has now become clear that many other molecules such as osteopontin that have functions in bone physiology also have important roles in the immune systems.
RANKL/RANK CONTROL OSTEOCLAST ACTIVATION AND BONE LOSS IN ARTHRITIS

Bone loss represents an important unsolved problem in rheumatoid arthritis (RA). The skeletal complications of RA consist of focal bone erosions and periarticular osteoporosis at sites of active inflammation, and generalised bone loss with reduced bone mass. Local bone loss at the affected joints frequently results in lifelong crippling. Arthritis in humans and animal models is characterised by synovial inflammation, erosion of bone and cartilage, severe joint pain, and ultimately lifelong crippling. For example, in Lewis rats, experimental induction of arthritis by subcutaneous injection of bacterial products in adjuvant leads to severe inflammation in the bone marrow and soft tissues surrounding joints accompanied by extensive local bone and cartilage destruction, loss of bone mineral density, and crippling. This condition in rats, called adjuvant induced arthritis, mimics many of the clinical and pathological features of human RA. Lesions in rat adjuvant induced arthritis are dependent on T cell activation, and T cells in the inflamed joints and draining lymph nodes of affected rats have been shown to produce many proinflammatory cytokines.

In the adjuvant induced arthritis model, RANKL protein is expressed on the surface of synovial effector T cells isolated at the clinical onset of arthritis. Inhibition of RANKL via OPG had no effect on the severity of inflammation. However, OPG treatment completely abolished the loss of mineral bone density in the inflamed joints of these animals in a dose dependent manner. Histologically, OPG treated arthritic animals exhibited minimal loss of cortical and trabecular bone, whereas untreated arthritic animals developed severe bone lesions characterised by partial to complete destruction of cortical and trabecular bone, and erosion of the articular cartilages. Bone destruction in untreated arthritic rats correlated with a dramatic increase in osteoclast numbers whereas OPG treatment prevented the accumulation of osteoclasts. These results showed that RANKL is a key mediator of joint destruction and bone loss in adjuvant arthritis. Importantly, whereas untreated rats experienced severe crippling, rats treated with OPG at the onset of disease—similar to a patient consulting a doctor at the onset of joint swelling—did not show any signs of clinical crippling.

Alteration of cartilage structures leading to cartilage collapse constitutes a critical step in arthritic joint destruction. Controversy exists whether cartilage destruction occurs independently of bone loss, or whether damage to the subchondral bone indirectly causes cartilage deterioration. In untreated arthritic rats, partial or complete erosion of the cartilage in both the central and peripheral regions of joint surfaces is observed. In striking contrast, neither cartilage erosion nor matrix degeneration in the centres of joint surfaces occurred in OPG treated animals. OPG could protect the cartilage by maintaining the underlying subchondral bone therefore insulating the overlying cartilage from the inflammatory cell infiltrates in the bone marrow. As both RANKL and RANK are expressed on chondrocytes, as well as rank mutant mice exhibit significant changes in the columnar alignment of chondrocytes at the growth plate, it is possible that RANKL/RANK play a direct part in cartilage growth and cartilage homeostasis. RANK, RANKL, and OPG expression have been recently observed in normal cartilage. However, the functional relevance of RANKL-RANK expression in chondrocytes is still not known. Thus, inhibition of RANKL activity by OPG can prevent cartilage destruction, a critical, irreversible step in the pathogenesis of arthritis.

Arthritis can occur in the absence of T cells. Using in situ hybridisation of inflamed rat joints and isolation of different cell populations from these joints, we could show that RANKL is indeed expressed in lymphocytes, macrophages, and especially in synoviocytes. In line with these findings, genetic ablation of RANKL does not prevent inflammation in an antibody mediated model of arthritis using the K/BxN serum transfer model. Multinucleated TRAP positive osteoclast-like cells were abundant in resorption lacunae in areas of bone erosion in arthritic control mice, and were completely absent in arthritic RANKL mutant mice, demonstrating the absolute requirement for RANKL in osteoclastogenesis in this serum transfer model of inflammatory arthritis. Cartilage damage was still observed in both arthritic TRANCE/RANKL knockout mice and arthritic control mice but a trend towards milder cartilage damage in the rankl− mice was noted. Thus, it seems that RANKL is not essential for cartilage destruction, but clearly plays a yet unidentified modulatory part.

It has recently been shown that interleukin 1 and to a lesser extent TNFα are critical mediators of antibody induced arthritis in the serum transfer model. Moreover, inhibition of RANKL via OPG prevents bone loss and has a beneficial effect on cartilage destruction without affecting inflammation in a TNFα induced arthritis model indicating that TNFα triggered joint destruction is critically dependent on RANKL expression. It has also been recently suggested that the RANKL-RANK system plays an important part for osteoclastogenesis in both local and systemic osteolytic lesions in autoimmune type II collagen induced arthritis in mice. Thus, in all animals for arthritis studied so far, the RANKL/RANK system is the trigger of bone loss and crippling making OPG the prime drug candidate for therapeutic intervention in different forms of arthritis.

To extend these rodent studies to human patients with arthritis, we collected inflammatory cells from the synovial fluids of patients with adult or juvenile RA and patients with osteoarthritis and evaluated OPG and RANKL expression. All RA patients and patients with advanced osteoarthritis tested (n>40) in our study exhibited RANKL expression in inflammatory cells while OPG expression was not detectable. Thus, the correlation between RANKL expression in inflamed joints and arthritis was absolute. To distinguish which cells were producing RANKL, inflammatory synovial fluids were separated into T cell and non-T cell populations. Consistent with our results in rats, both synovial T cell and non-T cell populations from RA patients expressed RANKL, but not OPG. In subsequent studies, it has been shown that synovial T cells, monocytes, and synovial fibroblasts express both membrane bound and soluble forms of RANKL and that RANKL mRNA is present in cells isolated from the pannus and synovial membrane regions of RA patients. Moreover, activated human T cells expressing RANKL can induce osteoclastogenesis from autologous peripheral monocytes, which can be blocked by dose dependent inhibition using OPG. These data confirm our initial findings in rodent adjuvant arthritis models, and suggest that RANKL is the principal mediator of bone destruction in human arthritis. Moreover, these results provide a unifying mechanism between T cell activation, cytokine production, and osteoclast activation and joint destruction via the RANKL/OPG/RANK ligand-receptor system that explains the spectrum of skeletal disorders in RA.

A MOLECULAR SCENARIO OF T CELL REGULATED BONE LOSS

In inflammatory or autoimmune disease states, activated T cells produce RANKL and proinflammatory cytokines such as TNFα, IL1, IL6, or IL11, all of which can induce RANKL expression in osteoblasts and bone marrow stromal cells. Thus, it seems that T cells promote bone resorption directly via RANKL expression and indirectly via expression of proinflammatory cytokines that mediate RANKL expression in non-T cells (from these joint cells, we could show that RANKL is expressed in lymphocytes, macrophages, and especially in synoviocytes. In line with these findings, genetic
Role of RANKL and RANK in bone loss and arthritis

However, short-term activation of T cells does not result in any detectable bone loss and even in some chronic T cell and TNFα mediated diseases such as ankylosis spondylitis, T cell activation does not result in bone loss. Moreover, T cells are working constantly to fight off the universe of foreign particles in which we live, so, at any point in time, some T cells are activated. So what is it that prevents these T cells from causing extensive bone loss every time we have an infection? A crucial counter-regulatory mechanism, by which activated T cells can inhibit the RANKL induced maturation and activation of osteoclasts has been recently discovered (fig 2). It turns out that interferon gamma blocks RANKL induced osteoclast differentiation in vitro. Moreover, interferon gamma receptor knockout mice develop more bone destruction in inflammatory arthritis than normal mice. Mechanistically, interferon gamma can activate the ubiquitin–proteasome pathway within the osteoclasts, resulting in the degradation of TRAF6. Thus, it seems that interferon gamma can prevent uncontrolled bone loss during inflammatory T cell responses. Moreover, T cell derived IL12 alone and IL12 in synergy with IL18 inhibits osteoclast formation in vitro and IL4 can abrogate osteoclastogenesis through STAT6 dependent inhibition of NFκB signalling. Thus, multiple T cell derived cytokine might be able to interfere with RANK signalling and therefore osteoclastogenesis and osteoclast functions. In the future it will be interesting to determine the mechanisms that control the balance between T cell mediated bone loss and inhibition of osteoclastogenesis.

CONCLUSIONS
It has become clear that inhibition of RANKL mediated activation of RANK via OPG or a related molecule ameliorates many osteopotic conditions. RANKL inhibition seems to be the most rational and advisable strategy to prevent bone destruction in multiple diseases and to possibly eradicate major human diseases such as osteoporosis and to curtail crippling in arthritis, diseases that affect millions of people.
