EXTENDED REPORT

Effect of non-steroidal anti-inflammatory drugs on radiographic spinal progression in patients with axial spondyloarthritis: results from the German Spondyloarthritis Inception Cohort

ABSTRACT

Objective To investigate the influence of non-steroidal anti-inflammatory drugs (NSAIDs) intake on radiographic spinal progression over 2 years in patients with ankylosing spondylitis (AS) and non-radiographic axial spondyloarthritis (SpA).

Methods 164 patients with axial SpA (88 with AS and 76 with non-radiographic axial SpA) were selected for this analysis based on availability of spinal radiographs at baseline and after 2 years of follow-up and the data on NSAIDs intake. Spinal radiographs were scored by two trained readers in a concealed randomly selected order according to the modified Stoke Ankylosing Spondylitis Spine Score (mSASSS) system. An index of the NSAID intake counting both dose and duration of drug intake was calculated.

Results High NSAIDs intake (NSAID index ≥50) in AS was associated with lower likelihood of significant radiographic progression defined as an mSASSS worsening by ≥2 units: OR=0.15, 95% CI 0.02 to 0.96, p=0.045 (adjusted for baseline structural damage, elevated C reactive protein (CRP) and smoking status) in comparison with patients with low NSAIDs intake (NSAID index <50). This effect was most pronounced in patients with baseline syndesmophytes plus elevated CRP: mean mSASSS progression was 4.36±4.53 in patients with low NSAIDs intake versus 0.14±1.80 with high intake, p=0.02. In non-radiographic axial SpA, no significant differences regarding radiographic progression between patients with high and low NSAIDs intake were found.

Conclusion A high NSAIDs intake over 2 years is associated with retarded radiographic spinal progression in AS. In non-radiographic axial SpA this effect is less evident, probably due to a low grade of new bone formation in the spine at this stage.

Non-steroidal anti-inflammatory drugs (NSAIDs) are considered as a preferred therapy in patients with axial spondyloarthritis (SpA), including ankylosing spondylitis (AS).1 However, it has been suggested that NSAIDs might have a good symptomatic and a disease-modifying effect. It had been shown in a small retrospective study by Boersma some time ago that a continuous use of phenylbutazone was associated with retardation of spinal ossification in AS.2 In a more recent study by Wanders et al, continuous (daily) use of NSAIDs was also associated with an inhibition of radiographic progression in the spine over 2 years as compared with on-demand use.3 However, these reports have not been confirmed until now. Furthermore, NSAIDs influence on radiographic progression in early axial SpA (especially in a non-radiographic form) was not investigated so far. This analysis of the 2-year data from the German Spondyloarthritis Inception Cohort (GESPIC) was aimed at investigating the influence of NSAIDs intake on radiographic progression of the spine in patients with AS and non-radiographic axial SpA with short disease duration.

METHODS

Patient selection

Patients included in GESPIC were required to have a definite clinical diagnosis of axial SpA according to the local rheumatologist. Patients were further classified based on radiographic findings as AS or as non-radiographic axial SpA. Patients with AS ought to fulfil the modified New York criteria4 and the duration of symptoms was restricted to ≤10 years at the time of inclusion. Patients with non-radiographic axial SpA ought to fulfil European Spondyloarthropathy Study Group criteria5 with minor modifications6 and had to have duration of symptoms of ≤5 years. The baseline data of this cohort have been recently reported elsewhere.6

Radiographs of the spine (lumbar and cervical spine) and sacroiliac joints were obtained at baseline and after 2 years of follow-up. The full sets of radiographs were available for 210 GESPIC patients (115 with AS and 95 with non-radiographic axial SpA) as reported elsewhere.7 Of these, information on NSAIDs intake over 2 years was available for 164 patients (88 with AS and 76 with non-radiographic axial SpA) who were naïve to antitumour necrosis factor (TNF) therapy and did not receive this therapy during 2 years of follow-up.

Radiographs and scoring

X-rays of sacroiliac joints and spine (cervical and lumbar spine at baseline and after 2 years of follow-up) were performed locally. Images were centrally collected, digitised, anonymised and subsequently scored independently by two trained readers (DP, HH). The readers scored radiographs in a concealed and randomly selected order and

Ankylosing Spondylitis Spine Score (mSASSS) scoring system. Eight radiographs were scored according to the modified Stoke Ankylosing Spondylitis Spine Score; NSAID, non-steroidal anti-inflammatory drug; SpA, spondyloarthritis.

Statistics

Status scores for baseline and follow-up were calculated by taking the mean of the scores of both readers. Radiographic progression was calculated by the difference between follow-up and baseline mean values. Agreement between readers was estimated by the intraclass correlation coefficient (ICC). Significant radiographic progression was defined as a worsening of the mSASSS score by ≥2 units over 2 years.8,10 Syndesmophytes were considered to be absent or present if both readers agreed on it.

X² test, Mann–Whitney U test and one-way analysis of variance were applied as appropriate. Non-parametric analysis of covariance11 was used to compare changes in mSASSS between groups after adjustment for mSASSS status at baseline. A multivariate logistic regression analysis was performed in order to analyse the influence of NSAIDs intake on radiographic spinal progression with adjustment for other factors. A p value of <0.05 was considered to be statistically significant.

Ethical approval

The study protocol was approved by the central ethical committee of the coordinating centre (Charité Universitätsmedizin Berlin, Berlin, Germany) and by all local ethical committees of the participating centres. Written informed consent was obtained from all patients.

RESULTS

The mean NSAID intake index over 2 years was 33.7±28.0 (range 0–100) in the AS and 52.2±26.7 (range 0–100) in the non-radiographic axial SpA group. Overall, 24 with AS (27.3%) and 19 patients with non-radiographic axial SpA (25.0%) had a high NSAIDs (NSAID intake index ≥50) intake during 2 years of follow-up. Comparative characteristics of patients with low and high NSAIDs intake are presented in table 1. As shown in the table, patients with a high NSAIDs intake had at baseline higher clinical disease activity (as measured by the Bath Ankylosing Spondylitis Disease Activity Index) and higher level of functional impairment (as measured by the Bath Ankylosing Spondylitis Functional Index) as compared with patients with low NSAIDs intake. Patients with AS and high NSAIDs intake had also numerically higher frequency of syndesmophytes at baseline and higher baseline mSASSS score. Other parameters were similar in the subgroups. Selective inhibitors of cyclo-oxygenase-2 (COX-2 inhibitors: celecoxib, etoricoxib, rofecoxib,

NSAIDs intake

Data on NSAIDs intake (dose and frequency of intake) were collected at baseline and every 6 months thereafter during 2 years of follow-up. An index of the NSAID intake,9 as recommended by ASAS (Assessment of SpondyloArthritis international Society), accounting for both dose and duration/regiment of drug intake (0: no NSAIDs intake at all, 100: daily NSAIDs intake in a dose equivalent to diclofenac 150 mg over the whole period of interest) was calculated. High NSAIDs intake was defined as a mean NSAIDs intake index ≥50, and low NSAIDs intake. Patients with AS and high NSAIDs intake had also numerically higher frequency of syndesmophytes at baseline and higher baseline mSASSS score. Other parameters were similar in the subgroups. Selective inhibitors of cyclo-oxygenase-2 (COX-2 inhibitors: celecoxib, etoricoxib, rofecoxib,
valdecoxib), as opposed to non-selective COX inhibitors, were used in similar proportions of patients with high and low NSAIDs intake: 29.2% and 32.1%, respectively, in AS; 42.1% and 33.3%, respectively, in non-radiographic axial SpA. Among non-selective COX inhibitors, diclofenac, ibuprofen, indomethacin and piroxicam were used most frequently and accounted for more than 50% of all NSAIDs used.

There was a very good agreement between the two readers regarding status scores (mSASSS) of spinal radiographic damage: the ICC was 0.92 (95% CI 0.90 to 0.94) at baseline and 0.92 (95% CI 0.89 to 0.94) at year 2. The agreement regarding the mSASSS change score was moderate with an ICC coefficient of 0.33 (95% CI 0.19 to 0.49).

The cumulative probability plot presented in figure 1A demonstrates the divergence of mSASSS change on the patient level with less radiographic progression in the group of AS patients with high NSAIDs intake. The mean mSASSS change over 2 years in AS was 0.02±1.39 in patients with high NSAIDs intake versus 0.96±2.78 in the subgroup with low NSAIDs intake, respectively; p=0.142 (after adjustment for radiographic status at baseline p=0.22) (figure 2A). The trend for reduced radiographic spinal progression in patients with high NSAIDs intake was also present if other thresholds for the index of NSAIDs intake were chosen (eg, tertiles). In AS patients with an NSAID intake index values of <33, 33–65 and ≥66, the mSASSS changes over 2 years were 0.86±2.93, 0.75±1.84 and 0.10±1.70 units, respectively.

In the current study, we present data showing that NSAIDs retard radiographic spinal progression as assessed by an mSASSS change over 2 years in patients with AS confirming, therefore, earlier data. Although the clear difference in the absolute mSASSS change between subgroups with high and low NSAIDs intake was statistically non-significant (probably due to a relatively low sample size and high variation of the radiographic progression), an analysis of significant radiographic progression (ie, mSASSS worsening in 2 units and more over 2 years) adjusted for factors predictive for radiographic spinal progression, especially for the presence of structural damage at baseline, revealed a significant association between high NSAIDs intake and radiographic progression in AS (OR=0.15, 95%
Clinical and epidemiological research

Figure 3  Radiographic spinal progression (change of the mSASSS score) over 2 years in relation to NSAID intake in AS patients with presence (A) and absence (B) of risk factors for progression (syndesmophytes at baseline and elevated time-averaged CRP). Each box indicates the median value, the first and the third quartiles; whiskers demonstrate minimal and maximal values, white dots inside the boxes – mean values, outside circles and asterisk – outliers. Low NSAID intake: NSAID intake index <50; high NSAID intake: NSAID intake index ≥50. Time-averaged CRP: CRP levels were determined at baseline and every 6 months thereafter during 2 years of follow-up. AS, ankylosing spondylitis; CRP, C reactive protein; mSASSS, modified Stoke Ankylosing Spondylitis Spine Score; NSAID, non-steroidal anti-inflammatory drug.

CI 0.02 to 0.96, p=0.045: table 2). Adjustment for baseline factors such as baseline damage, smoking and CRP was important because there was heterogeneity among the groups at baseline and because these factors have been shown to be predictors of progression. It was remarkable to see a retarding effect of NSAIDs particularly in the group of AS patients with high NSAID intake because these patients had a higher proportion of syndesmophytes (table 1) – the strongest predictor of progression as compared with smoking and CRP – and, therefore, were more likely to progress compared with patients with low intake of NSAIDs who had less frequently syndesmophytes.

In AS patients with normal CRP and/or no syndesmophytes at baseline there was nearly no radiographic progression independently from the NSAIDs intake. In contrast, the effect of high NSAIDs intake was most pronounced in patients with both syndesmophytes at baseline and elevated CRP, suggesting that the observed NSAID effect on radiographic progression is mostly driven by this subgroup, which constitutes 25% of the whole AS group in the current study. These data indicate that continuous NSAIDs intake might especially be of benefit in these patients.

In non-radiographic axial SpA, however, this effect could not be shown which is most likely related to a relatively low radiographic spinal progression rate in this subgroup in general and nearly no new bone formation (syndesmophytes) in particular. Furthermore, in this group the mSASSS might be more driven by erosive changes than by new bone formation.

Interestingly, there was also a trend towards reduced radiographic sacroiliitis progression in patients with AS and high NSAIDs intake, but this was not the case in non-radiographic axial SpA. We speculate that this could be related to the interference of the NSAIDs with the new bone formation, which is mostly responsible for radiographic progression in advanced sacroiliitis, as opposed to the destructive erosive change at the early disease.

In this analysis we used the recently introduced index of NSAIDs intake.9 This index accounts for dose and duration of NSAIDs intake which seem to be both relevant for retardation of radiographic spinal progression, since no clear differences in radiographic progression could be found if dose or duration of intake only were taken into account. The analysis with continuous variables (mean NSAIDs index over 2 years and mSASSS change score) demonstrated only a weak and statistically nonsignificant negative correlation between NSAIDs index and radiographic progression indicating a non-linear character of the relationship. Therefore, a clinically relevant threshold (NSAIDs intake index of 50) was chosen for this analysis to differentiate between low and high NSAID intake. Other thresholds (eg, tertiles) provided comparable results with the clearest effect of NSAIDs seen in the highest tertile, but the resulting patient numbers per group were too small to show significant differences.

Earlier investigations indeed already indicated that NSAIDs might have an inhibitory effect on new bone formation. There are several observational studies indicating a retardation of fracture healing35–39 or loosening of the hip endoprosthesis40 related to NSAIDs use. Furthermore, NSAIDs have been used for the prevention of heterotopic ossification after orthopaedic surgery, for example, total hip arthroplasty,18–25 hip resurfacing26 or fractures (eg, acetabular fractures).27 28

The observed inhibition of new bone formation by NSAIDs can probably best be explained by the inhibition of prostaglandins (especially prostaglandin E2) synthesis mediated by COX-2.39 Prostaglandin E2 is able to stimulate new bone formation by increasing the replication and differentiation of osteoblasts.30

Prostaglandins also support blood supply to the site of new bone formation by causing vasodilatation and by promoting angiogenesis.31 32 In experiments with COX-2 knockout mice, healing of the stabilised tibia fracture was delayed in comparison with wild-type animals and to COX-1 knockouts.33 Similarly, NSAIDs were able to retard a bone morphogenetic protein 7 induced ectopic

bone formation in an experimental mouse model indicating an important role of COX-mediated prostaglandin synthesis in new bone formation. If retardation of the new bone formation is related to COX-2 inhibition, no substantial differences are expected between different NSAIDs, because in therapeutic concentrations all NSAIDs, independently from their COX-selectivity, inhibit COX-2 to nearly the same extent. NSAIDs are considered as a preferred therapy in patients with axial SPA due to their high symptomatic activity. In addition, small but significant decrease of CRP has been seen in AS patients treated with NSAIDs. If the structure-modifying effect of NSAIDs in AS is confirmed, it would be an additional argument to administer NSAIDs more, especially in patients with clinical indications for NSAIDs and in patients who are at risk for radiographic spinal progression such as presence of syndesmophytes and/or an elevated level of acute phase reactants. The potential cardiovascular, gastrointestinal and other side effects of continuous NSAIDs intake have been investigated in the greatest detail and we have argued recently that the benefit of such a treatment normally outweighs the risk in AS. The data presented here add further evidence to this.

Due to the character of our study there are some limitations which might have influenced the final results. GESPIC is an observational cohort and includes therefore a relative heterogeneous (in comparison with ‘standard’ drug investigating clinical trials) patient population, which was included based on diagnosis and symptom duration without further limitations. On the other hand, this comes closer to daily clinical practise. GESPIC was not specially designed and powered for the investigation of the influence of NSAIDs on radiographic progression. The NSAIDs doses and duration of intake were not strictly counted, but relied on the information given by the patient every 6 months, and represent therefore the best possible approximation. Finally, the treatment with NSAIDs was heterogeneous with a variety of NSAIDs used, but again this is closer to daily clinical practise.

In conclusion, we add further evidence here that NSAIDs seem to retard new bone formation in AS patients. Given the good anti-inflammatory capacity of TNF blockers in AS but their failure in stopping new bone formation, a trial combining TNF blocker and NSAIDs treatment would especially be of interest addressing the question whether new bone formation can be inhibited, in addition to suppressing inflammation and improving signs and symptoms.
