ABSTRACT

Objectives To characterise optimal screening strategies for latent tuberculosis infection (LTBI) prior to the initiation of anti-tumour necrosis factor therapy.

Methods Patients in 62 German rheumatology centres were evaluated for LTBI. Each patient was screened with a tuberculin skin test (TST) and one form of an interferon-\(\gamma\)-release assay (IGRA), either TSPOT.TB (TSPOT) or Quantiferon TB Gold (QFT).

Results A total of 1529 patients with rheumatological disease were tested with a TST, 844 with TSPOT and 685 with QFT. TST was positive in 11.3% (n=173). The prevalence of LTBI was 8.0% when defined as a positive TST and no previous Bacille Calmette-Guérin (BCG) vaccination and 7.9% when based on a positive IGRA. Combining both estimates increased the prevalence of LTBI to 11.1%. Clinical risk factors for LTBI were found in 125 patients (34 with a history of prior TB, 81 close contacts and 27 with suggestive chest x-ray lesions). A compound risk factor (CRF) was defined as the presence of at least one of these three risk factors. Statistical analyses were conducted to examine the association between CRF and LTBI test outcomes. In multivariate analysis, TST was influenced by CRF and LTBI test outcomes. In multivariate analysis, TST was influenced by CRF and LTBI test outcomes. In multivariate analysis, TST was influenced by CRF and LTBI test outcomes. In multivariate analysis, TST was influenced by CRF and LTBI test outcomes.

METHODS

Study design and patients

This was a prospective study in which patients eligible for anti-TNF agents were successively screened for LTBI at 62 participating centres located throughout Germany according to standard of care and national recommendations. Ethical approval for data management was obtained from the Ethics Committee of the Charité – Universitätsmedizin Berlin and approval for secure data management procedures was obtained from the data protection officer.

LTBI screening

Patients were screened for LTBI according to national guidelines. The patient’s history of prior TB and close contact with TB patients was noted and Bacille Calmette-Guérin (BCG) vaccination status was documented. All patients underwent physical examination. Chest x-rays were obtained from 1409 patients. Interpretation regarding pulmonary lesions suggestive of latent or prior TB was based on the judgement of the local radiologist.

All patients received a TST and one type of IGRA, either TSPOT.TB (TSPOT) or Quantiferon TB Gold (QFT), depending on what was available in the corresponding laboratory. In accordance...
Clinical and epidemiological research

with contemporary guidelines for immunosuppressed patients, a TST with a diameter of >5 mm skin induration was considered positive. The cut-off for TSPOT positivity was ≥6 spots. At the time of testing, IGRA were mainly based on the two peptide antigens ESAT-6 and CFP-10.

Statistical analyses

Clinical risk factors for LTBI were defined as a history of prior TB (prior TB), close contact to a patient with TB (contact) or a chest x-ray suggestive of LTBI (CXR). A compound risk factor (CRF) was defined as the presence of at least one of these three risk factors.

Statistical analyses were performed using SPSS V.17.02 for Windows (SPSS, Chicago, Illinois, USA). Univariate regression analyses were used to calculate the influence of single risk factors; multivariate analyses used the variables CRF and BCG vaccination status to estimate the influence on test results. The results were reported as OR with CI. Cohen’s k was calculated for test agreement (higher values indicate greater agreement).

Lymphocyte count and prednisone dose at the time of testing were documented in a subset of patients, and regression analyses were used to calculate the influence of these factors on OR for a negative or indeterminate test result.

RESULTS

Patient characteristics

A total of 1609 patients eligible for anti-TNF treatment were successively screened for LTBI. Eighty patients were excluded from the main analysis due to indeterminate IGRA results, leaving a total of 1529 patients. All of the patients had rheumatic diseases, including rheumatoid arthritis (RA; n=852, mean DAS28 4.35±1.88, median disease duration 7.4 years), ankylosing spondylitis (AS; n=294, median disease duration 7.5 years), psoriatic arthritis (PsA; n=215, median disease duration 6.9 years), undifferentiated spondyloarthritis (SpA; n=92, median disease duration 3.6 years) and various other rheumatologic disorders (n=76, median disease duration 1.3 years). More than half of the patients (61.3%) were women. Of the 1529 patients, 204 (13.3%) had been vaccinated with BCG. Patient characteristics and risk factors by TST and IGRA status are shown in figure 1.

Estimation of LTBI prevalence

Positive TSTs were recorded in 11.3% (n=173) of patients positive for both TST and IGRA.

Influence of risk factors on test results

Clinical risk factors for LTBI were found in 122 patients (34 with a history of prior TB, 81 close contacts and 27 with a chest x-ray suggestive of LTBI). A CRF was defined as the presence of at least one of these risk factors. Risk factors were more common in patients with positive LTBI screening results (table 1).

Statistical analyses were used to examine the impact of risk factors on screening results. For TST and TSPOT, all single risk factors influenced test results while, for QFT, only the risk factor prior TB had an influence on test results (see table S1 in online supplement).

We further analysed the influence of CRF and BCG vaccination status on the LTBI screening results. In multivariate analyses, patients with CRF had a 6.2-fold increased risk for positive TST in the total population (table 2). CRF was associated with a 2.6-fold increased risk for a positive QFT and an 8.7-fold increased risk for positive TSPOT.

Data represent patient numbers (%) positive for vaccination or stated risk factor unless otherwise indicated.

CRF was defined as the presence of at least one of the following three clinical risk factors: history of prior TB, close contact and chest x-ray suggestive of LTBI (CXR).

1 Twenty-one patients had missing data on BCG vaccination (2 in the TST-positive group and 19 in the TST-negative group). Eighteen of the 21 patients were tested with QFT (1 positive, 17 negative) and the remaining 3 were tested with TSPOT (1 positive, 2 negative).

1 Five patients had missing results on prior TB/contact and therefore also on CRF. All 5 were in the TST-negative group (2 in the QFT-negative group, 2 in the TSPOT-negative group and 1 in the TSPOT-positive group).

1 Chest x-ray was performed in 88.2–97.1% of patients in each group.

risk for a positive TSPOT. Univariate analyses revealed very similar results (data not shown). Test results were independent of the time interval between TST and IGRA (p=0.21; data not shown).

### Influence of risk factors in disease subgroups

Multivariate regression analyses of patients with RA (n=852) showed that CRF influenced TST (OR 8.44, CI 4.71 to 15.14, p<0.001) and TSPOT (OR 10.65, CI 5.01 to 22.81, p<0.001) but not QFT (OR 0.69, CI 0.08 to 4.66, p=0.625). In patients with PsA (n=215), CRF had no significant influence on TSPOT (OR 3.54, CI 0.56 to 22.33, p=0.179) or TST (OR 1.98, CI 0.61 to 6.38, p=0.253) and could not be calculated for QFT due to the absence of patients with CRF and positive QFT. In patients with AS or SpA (n=385), CRF influenced TST (OR 7.88, CI 3.44 to 18.05, p<0.001), TSPOT (OR 7.03, CI 2.76 to 17.89, p<0.001) and QFT (OR 7.29, CI 2.87 to 18.52, p<0.001). Complete disease subgroup data are shown in table S2 in the online supplement. Univariate results were very similar.

### Agreement between TST and IGRA

The patients’ characteristics in the concordant and discordant subgroups are shown in table 3. Concordance of TST and IGRA was 89.5% but Cohen’s κ was 0.40 (p=0.001), indicating that the agreement was only fair to moderate, although significant. Concordance was 87.6% (κ=0.34, p<0.001) between TST and QFT and 91.1% (κ=0.44, p<0.001) between TST and TSPOT. Agreement was significant in the total population and all disease subgroups except those with PsA (see table S3 in online supplement). The subgroup of TST-positive patients with a skin induration ≥15 mm (n=71) included 27 that were not BCG vaccinated and were IGRA-negative.

### Influence of BCG vaccination

Of the 204 patients who were BCG vaccinated, 50 were TST-positive and 14 were IGRA-positive (table 1). BCG status influenced TST but not QFT and TSPOT (table 2). Concordance was lower in the BCG vaccinated group (79.9%, p=0.001) than in the non-vaccinated group (n=1303; 91.0%, p=0.45, p<0.001).

### Influence of lymphocyte count and prednisone dose on test results

In a subgroup analysis of 507 patients with data on prednisone dose and lymphocyte counts, ORs for negative or indeterminate test results were not affected by low lymphocyte count (compared with a normal lymphocyte count) or the use of prednisone (compared with non-use) (see table S4 in online supplement).

### DISCUSSION

Testing for LTBI using the classical risk factors and TST has been proved to reduce the incidence of TB reactivation in patients treated with TNF inhibitors. IGRAs have shown superior results for screening after TB exposure, but their utility in LTBI screening in everyday practice has not been well studied, particularly with respect to detecting LTBI and preventing TB reactivation in patients preparing to start anti-TNF treatment. Because there is no ‘gold standard’ for diagnosing LTBI, it is not possible to determine whether discrepancies among test systems reflect false positives or false negatives or to calculate the sensitivity and specificity of TB test systems. To gain a better understanding of optimal LTBI screening methods, we therefore compared the performance of TST and IGRA (either TSPOT or QFT) in a multicentre study of 1529 consecutive German patients with rheumatological disease tested for LTBI prior to anti-TNF treatment and analysed the impact of BCG vaccination and LTBI risk factors on screening results.

For our analysis of different LTBI screening systems in a country with a low incidence of TB, we used a positive TST without previous BCG vaccination or a positive IGRA as surrogate definitions for LTBI, although this is not recommended in clinical practice. In particular, in populations with high incidences of TB, it is recommended that a positive TST in the absence of active TB should be classified as LTBI regardless of prior BCG vaccination.

Our study revealed an LTBI prevalence of 8.0% based on TST/BCG vaccination status and 7.9% based on IGRA testing. When LTBI was defined as a positive response in either test system, the prevalence rate increased to 11.1%. These prevalence

Data represent patient numbers (%). Positive for vaccination or stated risk factor unless otherwise indicated.

CRF was defined as the presence of at least one of the following three clinical risk factors: history of prior TB, close contact and chest x-ray suggestive of LTBI (CXR). A positive QFT and pulmonary infiltrates on chest radiograph were used to define LTBI.

---

**Clinical and epidemiological research**
rates are comparable to those from a German study in which an LTBI prevalence of 7.2% (defined by QFT testing) was reported among healthcare workers.10

Owing to the lack of a gold standard for LTBI testing, we calculated the association between positive results and known LTBI clinical risk factors (prior TB disease, contact history and chest X-ray lesions suggestive of latent or prior TB) to help assess the performance of these testing systems. All the risk factors influenced the test results for TST and TSPOT whereas, for QFT, only prior TB exerted an influence. CRF influenced the results for all three of the tests but had less influence on QFT than on the other test systems. It should be noted that our study was not designed to compare the two IGRA systems (QFT and TSPOT) directly, so the correlation of clinical risk factors with test results provided the only means of estimating their relative utility. By this standard, TSPOT appears to perform better than QFT due to its greater correlation with known LTBI risk factors. Nevertheless, we cannot exclude the possibility that a poorer correlation with clinical risk factors is due to a higher specificity rather than a lower sensitivity. A better understanding of the relative merit of QFT versus TSPOT will require head-to-head tests under real-world conditions.

Important differences in the influence of risk factors on screening results and concordance of TST and IGRAs were observed among disease subgroups. In the RA subgroup, QFT was not influenced by CRF. In the PsA subgroup, CRF did not influence any test and concordance of TST and IGRAs was not significant whereas, in the SpA group, the influence of CRF on all tests was high. These discrepancies could indicate unknown confounders due to immunological disease characteristics or to the intensity and duration of previous immunosuppressive therapies. Our findings suggest that optimal LTBI screening strategies for patients with PsA may be particularly elusive.

A subgroup analysis of 507 patients with appropriate data did not reveal a statistically significant influence of prednisone use or lymphopenia on test results. Data on previous therapies and concomitant disease-modifying antirheumatic drugs were not recorded completely and therefore were not analysed.

Our study has some limitations that should be considered when evaluating the findings. The lack of a gold standard for LTBI diagnosis means that we cannot directly determine the sensitivity or specificity of the LTBI tests, nor were we able to obtain subsequent clinical information on the development of TB in these patients. In addition, the multicentre nature of our study, which involved the use of many different clinicians administering tests and laboratories assessing results, may add some unknown confounders but definitely resembles real-life conditions. Finally, these results were obtained in a country with a low incidence of TB and therefore preventing TB reactivation in patients prior to biological therapy requires further study. LTBI may have the additional benefit of detecting latent infection with atypical mycobacteria whereas IGRA does not. However, the impact of anti-TNF treatment on these infections needs further elucidation.

We conclude that, in patient populations with low rates of TB incidence and BCG vaccination, employing both TST and IGRA may maximise sensitivity in detecting LTBI but may also reduce specificity. From the clinician’s perspective, it is important to bear in mind that false positive or false negative tests can occur with either IGRA or TST. Accordingly, test results in each individual patient should be considered in the context of BCG vaccination status and probable LTBI risk as defined by clinical risk factors.
