ABSTRACT

Objectives HLA-DRB1*03 is strongly associated with anti-Jo-1-positive idiopathic inflammatory myopathies (IIM) and there is now increasing evidence that Jo-1 antigen is preferentially expressed in lung tissue. This study examined whether smoking was associated with the development of anti-Jo-1 antibodies in HLA-DRB1*03-positive IIM.

Methods IIM cases were selected with concurrent information regarding HLA-DRB1 status, smoking history and anti-Jo-1 antibody status. DNA was genotyped at DRB1 using a commercial sequence-specific oligonucleotide kit. Anti-Jo-1 antibody status was established using a line blot assay or immunoprecipitation.

Results 557 Caucasian IIM patients were recruited from Hungary (1811), UK (99), Sweden (94) and Czech Republic (183). Smoking frequency was increased in anti-Jo-1-positive IIM cases, and reached statistical significance in Hungarian IIM (45% Jo-1-positive vs 17% Jo-1-negative, OR 3.94, 95% CI 1.53 to 9.89, p<0.0001). A strong association between HLA-DRB1*03 and anti-Jo-1 status was observed across all four cohorts (DRB1*03 frequency: 74% Jo-1-positive vs 35% Jo-1-negative, OR 3.94, 95% CI 1.53 to 9.89, p<0.0001). A strong interaction was noted between smoking and DRB1*03-positive smokers vs DRB1*03-negative non-smokers (42% vs 8%, OR 7.75, 95% CI 4.21 to 14.28, p<0.0001). The frequency of anti-Jo-1 was increased in DRB1*03-positive smokers vs DRB1*03-negative non-smokers (42% vs 8%, OR 7.75, 95% CI 4.21 to 14.28, p<0.0001) and DRB1*03-positive non-smokers (42% vs 31%, p=0.08). In DRB1*03-negative patients, anti-Jo-1 status between smokers and non-smokers was not significantly different. No significant interaction was noted between smoking and DRB1*03 status using anti-Jo-1 as the outcome measure.

Conclusion Smoking appears to be associated with an increased risk of possession of anti-Jo-1 in HLA-DRB1*03-positive IIM cases. The authors hypothesise that an interaction between HLA-DRB1*03 and smoking may prime the development of anti-Jo-1 antibodies.

The idiopathic inflammatory myopathies (IIM) are a group of rare and heterogeneous autoimmune diseases characterised by inflammation of skeletal muscle, other organ systems and associated with significant co-morbidities. The aetiology of IIM remains poorly understood, but is likely due to interactions between genetic and environmental factors. IIM may be broadly classified according to the traditional clinical subtypes: polymyositis, dermatomyositis, myositis overlapping with another connective tissue disease (CTD), inclusion body myositis and juvenile dermatomyositis.

However, serological status according to circulating myositis-specific antibodies (MSA) or myositis-associated antibodies (MAA) is being increasingly used in the classification of IIM subtypes, and often correlates with well-defined IIM clinical phenotypes. For example, anti-aminocarboxyl tRNA synthetase antibodies are highly specific for IIM and define a clinical subtype labelled the ‘anti-synthetase syndrome’, characterised by Raynaud’s phenomenon, mechanics’ hands, arthropathy, interstitial lung disease and myositis.3 The most frequently found anti-aminocarboxyl tRNA synthetase antibody is the anti-histidyl tRNA synthetase (Jo-1) antibody. Alleles forming part of the Caucasian MHC 8.1 common ancestral haplotype (HLA-A1-B8-Cw7-DRB1*0301-DQA1*0501-DQB1*0302) occur in strong linkage disequilibrium within Caucasian populations in northern and western Europe, and represent risk factors for a large number of immunopathological diseases.3 To date, the 8.1 common ancestral haplotype has also been identified as the major risk factor in IIM.4–11 HLA alleles are also associated with the development of MSA/MAA in IIM, and the strong association of anti-aminocarboxyl tRNA synthetase antibodies and alleles comprising the 8.1 common ancestral haplotype has been confirmed in several IIM studies.2 6 12–15

The question arises as to whether and how anti-Jo-1, an antibody against a ubiquitous cytoplasmic antigen, may play a pathogenic role in IIM. In the development of rheumatoid arthritis (RA), an interaction between smoking and alleles forming the HLA shared epitope is thought to prime the development of anti-citrulline-positive antibodies.16 That Jo-1 is preferentially expressed in lung tissue17 18 is of potential relevance, bearing in mind that interstitial lung disease may be present in up to 70% of anti-Jo-1-positive patients.19

The current study investigated the hypothesis that a gene–environmental interaction between HLA-DRB1*03 and smoking could be of relevance in the development of anti-Jo-1 antibody-positive IIM.
RESULTS

Clinical subgroups
A total of 557 Caucasian adult-onset IIM patients (women 75%) was recruited from the following countries: Hungary (181), Czech Republic (165), Sweden (94), UK (99) (table 1). The median age of disease onset was 48 years (interquartile range 37–58). No significant difference was noted in the gender or age at onset distribution between the cohorts (p=0.065). Fifty per cent of the patients were classified as having polymyositis, 38% dermatomyositis and 12% myositis–CTD overlap disease. A stratification of clinical subgroup status by each participating country is summarised in table 1. An overall difference was present in the distribution of clinical subgroups (p<0.0001). Comparing the Hungarian cohort with other countries combined, the frequency of dermatomyositis was lower and myositis–CTD overlap higher in the Hungarian group. Within the Czech cohort, the dermatomyositis frequency was higher and myositis–CTD overlap frequency lower. Some variation was noted in the frequency of HLA-DRB1*03 between the European cohorts (Hungary, 32.0%; Czech Republic, 43.2%; Sweden, 54.3%; UK, 52.5%; see supplementary table S1, available online only).

Relationship between smoking and anti-Jo-1
The frequency of anti-Jo-1 antibodies was 21% for the overall group (table 2). The highest frequency was noted in the Czech cohort, and the lowest in the Swedish cohort. The frequency of anti-Jo-1 between the countries was broadly similar, although a significant difference was noted in the overall distribution. The overall frequency of ‘ever smoking’ was 39% and an overall significant difference was noted in the overall distribution. The overall frequency of ‘ever smoking’ was 39% and an overall significant difference was noted in the overall distribution. The overall frequency of ‘ever smoking’ was 39% and an overall significant difference was noted in the overall distribution. The overall frequency of ‘ever smoking’ was 39% and an overall significant difference was noted in the overall distribution.
Relationship between HLA-DRB1*03 and anti-Jo-1

As expected from previous work, a strong association between HLA-DRB1*03 and anti-Jo-1 was observed across all four cohorts combined (DRB1*03 frequency 74% Jo-1-positive cases vs 35% Jo-1-negative cases, OR 5.55, 95% CI 3.42 to 9.14, p=1.3×10**−14**).

Relationship between HLA-DRB1*03 and smoking

HLA-DRB1*03 was further examined by smoking status. The frequency of HLA-DRB1*03 was increased in smokers, and this association again reached statistical significance in Hungarian IIM (DRB1*03 frequency 59% smokers vs 25% non-smokers, OR 4.39, 95% CI 2.62 to 7.28, p<0.0001).

Investigation of risk of developing anti-Jo-1 antibody conferred by HLA-DRB1*03 and smoking

An analysis was then conducted to examine further the interrelationship between smoking and HLA-DRB1*03, and the risk of the development of anti-Jo-1 antibodies. For the purposes of this analysis, and to maximise statistical power, the four EU cohorts were combined. The HLA-DRB1*03 negative/non-smokers were used as the reference group for these comparisons. The frequency of anti-Jo-1 was significantly increased in both DRB1*03-positive smokers and non-smokers versus DRB1*03-negative non-smokers (table 3). In DRB1*03-negative patients, no significant difference was noted in anti-Jo-1 status between smokers and non-smokers. The frequency of anti-Jo-1 was increased in the DRB1*03-positive group who smoked compared with DRB1*03-positive non-smokers, although this trend did not achieve statistical significance (p=0.08). A similar trend was noted when a separate analysis was made of men and women (table 4). An interaction term was then created between ever-smokers and DRB1*03 status, using anti-Jo-1 as the outcome measure, but no multiplicative effect was observed between smoking and DRB1*03.

DISCUSSION

In four independent European IIM cohorts, the frequency of anti-Jo-1 antibody was approximately 20% in adult-onset disease. Intriguingly, it was observed that the frequency of anti-Jo-1-positive IIM cases across all four cohorts. The frequency of HLA-DRB1*03 was significantly increased in IIM patients who were smokers in the Hungarian cohort. The frequency of anti-Jo-1 antibody was in fact highest in HLA-DRB1*03-positive smokers compared with the other groups. These findings therefore suggest that smoking may only confer a risk of IIM in HLA-DRB1*03-positive individuals, or alternatively that smoking is a confounding variable for another factor that we did not investigate, for example, interstitial lung disease. Using a statistical interaction term, a relationship was not established between smoking and HLA-DRB1*03, but nevertheless these results do suggest that there is an additional risk of the development of anti-Jo-1 in HLA-DRB1*03-positive cases who are ever-smokers.

The design of the study implies a number of limitations. Environmental triggers may have conferred risk years before IIM onset, therefore it would have been desirable to quantify the number of cigarettes and at what point they were smoked before the onset of IIM accurately. This would have allowed an examination of any cumulative effects of smoking on risk and to assess any temporal relationship of smoking with IIM onset or the commencement of anti-Jo-1 positivity. Examining these issues would, however, only be possible as part of a detailed prospective study. Our study was able to establish that smoking does appear to represent a risk factor for the development of anti-Jo-1 antibodies, but due to a lack of a matched control population, we were not able to establish that smoking was a risk factor per se for IIM, as has been demonstrated in other autoimmune diseases. We aim to address this issue as part of a future study. Furthermore, this particular study has not examined other possible MSA/MAA as part of an interaction with smoking. It is possible that in this study, HLA-DRB1*03 may be a marker for a different allele in which linkage disequilibrium is shared. A further issue is the heterogeneity of the HLA class II distribution and the variation of smoking frequency across all four cohorts combined (DRB1*03 frequency 74% Jo-1-positive cases vs 35% Jo-1-negative cases, OR 5.55, 95% CI 3.42 to 9.14, p=1.3×10**−14**).

HLA-DRB1*03-positive cases assigned if they possess one or two copies of DRB1*03.
on the multiplicative scale was not proved to be statistically significant, but this may be due to a lack of statistical power. We also estimated the interaction between HLA-DRB1*03 and smoking on the additive scale (data not shown), in which there was a tendency towards an interaction but this was not statistically significant.

Smoking has been shown to induce disease development in other rheumatic diseases. A number of case–control and cohort studies have confirmed the association of smoking with the development of RA. Furthermore, a large case–control study has confirmed a high risk of developing anti-citrullinated antibody-positive RA conferred by a gene–environmental interaction between smoking and HLA-DR shared epitope genes. A further remarkable finding in this study was a high detected proportion of citrulline-positive bronchoalveolar lavage cells in healthy smokers. A further study has shown an association between smoking and systemic lupus erythematosus, and more specifically the occurrence of anti-double-stranded DNA antibodies.

The question arises as to whether smoking may have aetiological significance in IIM, for example, by inducing immunomodulatory effects in lung tissues. The Jo-1 antigen is known to be expressed in normal and cancerous lung tissue from non-IIM individuals in higher amounts than observed in other tissues. Granzyme B, a serine protease, is a critical component of the cytotoxic T-cell granule exocytosis pathway, and is thought to mediate muscle cell apoptosis.

Most autoantigens targeted in systemic autoimmune diseases, including several aminoacyl RNA synthetases, are substrates of granzyme B. Jo-1 appears to be uniquely cleaved by granzyme B in position 48 of the N-terminal domain. Furthermore, a unique granzyme B-cleavable form of Jo-1 is found in alveolar body and/or HLA-DRB1*03 positive. There is a suggestion that the risk of the development of anti-Jo-1 antibodies is further increased in IIM patients who are both smokers and possess one or more copies of HLA-DRB1*03. This may have aetiological significance in the development of IIM and may point towards a gene–environmental interaction. Future larger scale work is now required in larger patient cohorts, and in which the effects of other HLA genes and associated antibodies are testable with respect to smoking associations.

Acknowledgments The authors thank Arthritis Research UK (16082 to HC) for providing the infrastructure that made the UK collection of adult myositis patients’ DNA samples possible and the Myositis Support Group (UK), which provided the funds necessary to undertake the genetic analysis presented. The authors also thank the UK physicians who contributed to the Adult Onset Myositis Immunogenetic Collaboration.

Funding This study received funding from the Myositis Support Group (UK). J.V receives institutional support MSM 0021620812 from the Ministry of Education, Youth and Sports in the Czech Republic. The Swedish study has received funding from the Swedish Research Council, the Swedish Rheumatism Association, King Gustaf V 80 Year Foundation, Funds at the Karolinska Institutet, the European Union Sixth Framework Programme (Project AutoCure; LSH-016861), and through the regional agreement on medical training and clinical research (ALF) between Stockholm County Council and Karolinska Institutet. The Hungarian study was supported by a ETT 2 FAE 1 KD0098019 grant.
