Obesity and the risk of psoriatic arthritis: a population-based study

Thorvardur Jon Love,1 Yanyan Zhu,2 Yuqing Zhang,2 Lindsay Wall-Burns,3,4 Alexis Ogdie,5 Joel M Gelfand,6 Hyon K Choi7

ABSTRACT

Background Obesity is associated with an increased risk of psoriasis; however, its potential impact on the risk of psoriatic arthritis (PsA) remains unclear.

Objectives To evaluate the association between body mass index (BMI) and the risk of PsA among patients with psoriasis from the general population.

Methods The authors conducted a cohort study using data from The Health Improvement Network, an electronic medical records database representative of the UK general population, collected between 1995 and 2010. The exposure of interest was the first BMI measured after psoriasis diagnosis and endpoints were incident cases of physician-diagnosed PsA. The authors estimated the RR of PsA after adjusting for age, sex, and histories of trauma, smoking and alcohol consumption.

Results Among 75 395 individuals with psoriasis (43% male, mean follow-up of 5 years, and mean age of 52 years), 976 developed PsA (incidence rate, 26.5 per 100 000 person-years). The PsA incidence rates increased with increasing BMI. Compared with psoriasis patients with BMI <25 kg/m², the RRs for developing PsA were 1.09 (0.93–1.28) for BMIs from 25.0 to 29.9, 1.22 (1.02–1.47) for BMIs from 30.0 to 34.9 and 1.48 (1.20–1.81) for BMIs ≥35.0. In our secondary analysis among all individuals, regardless of psoriasis (~2 million), those with PsA had a higher body mass index (BMI) than healthy controls,12 and patients with PsA have a 61% higher odds of having obesity than psoriasis patients.13 A case series study (n=197 for PsA) reported that recalled BMI at 18 years of age was associated with an increased risk of PsA, whereas current BMI was not.14

Conclusions This general population study suggests that obesity is associated with an increased risk of PsA and supports the importance of weight reduction among psoriasis patients who often suffer from the metabolic syndrome and obesity.

INTRODUCTION

Psoriatic arthritis (PsA) is a progressive and often destructive inflammatory joint disease associated with psoriasis.1–3 The inflammatory arthritis of PsA adds substantially to the disease burden for psoriasis patients, with frequent joint destruction associated with cartilage erosions, bone damage and joint fusion. The negative impact of psoriasis may not be limited to its cutaneous or psychosocial manifestations,4 with emerging evidence indicating that psoriasis is associated with the metabolic syndrome5–6 and may lead to myocardial infarction,7 hypertension and diabetes.8 Despite these lifelong burdens of PsA, its causes and risk factors are poorly understood with a lack of large-scale data.

PsA is common in patients with psoriasis, affecting about 6–10% of psoriasis patients overall and substantially more patients with more extensive skin disease (up to 40%).1–3 In most patients with PsA, the symptoms do not develop until years after the onset of cutaneous psoriasis. As a result, patients with psoriasis represent a unique opportunity to study individuals at very high risk of developing a chronic inflammatory arthropathy (ie, PsA).1 To determine which patients with psoriasis are at the greatest risk of developing PsA, it is essential that risk factors be identified using robust epidemiological approaches.1

The adipose tissue in obese individuals is a site of overproduction of important inflammatory cytokines such as tumour necrosis factor α, interleukin 1, IL-6 and IL-8,9,10 and the resulting abnormal inflammatory milieu may contribute to the pathophysiology of psoriatic conditions.10 Obesity has been found to be associated with an increased risk of psoriasis,11 but its link to the risk of PsA remains less clear. Recent cross-sectional studies have found that PsA patients have a higher body mass index (BMI) than healthy controls,12 and patients with PsA have a 61% higher odds of having obesity than psoriasis patients.13 A case series study (n=197 for PsA) reported that recalled BMI at 18 years of age was associated with an increased risk of PsA, whereas current BMI was not.14

In this study, we examined the relation between BMI and the risk of incident PsA among 75 595 individuals with psoriasis from the general population.

METHODS

Study population

The Health Improvement Network (THIN) is a computerised medical record database entered by general practitioners (GP) in the UK. Data on approximately 7.3 million patients are systematically recorded and sent anonymously to THIN. Because the National Health Service in the UK requires every individual to be registered with a GP regardless of health status, THIN is a population-based cohort representative of the UK general population. The computerised information includes demographics, details from GPs’ visits, diagnoses from specialists’ referrals and hospital admissions, results of laboratory tests, and additional health information recorded systematically including height, weight, blood pressure, smoking and vaccinations. The Read classification is used to code specific diagnoses, and a drug dictionary based on data...
Clinical and epidemiological research

from the Multilex classification is used to code drugs. Health information is recorded on site at each practice using a computerised system with quality control procedures to maintain high data completion rates and accuracy. Thus, THIN data represent routine medical practice in a population-based setting.

Our primary study population consisted of psoriasis patients aged 20–89 years and enrolled in THIN at any time between January 1995 and May 2010 (n=75 955). Our secondary study populations included the cohort of individuals with or without psoriasis at baseline (N=2 026 139) and that limited to patients with incident psoriasis (n=27 980). Study cohort members had to be free of PsA before entering the study and were required to have two or more years of enrolment with the GP to help ensure exclusion of prevalent PsA. An individual’s start (index) date corresponded to the date of the first recorded BMI after all these eligibility criteria were met. Members of this cohort were followed until the date of one of the following endpoints: PsA diagnosis, 90th birthday, death or end of study period, whichever came first.

Ascertaining of psoriasis and PsA

Validity of THIN Read codes for psoriasis has been documented based on a sample of 4900 psoriasis patients. With a 95% response rate in a GP survey for clinical confirmation of psoriasis, the Read codes for psoriasis in THIN showed a positive predictive value (PPV) of 90% of clinical confirmation. Therefore, we defined psoriasis based on its Read code in THIN.

Although validity of PsA Read codes has not been assessed in THIN, the positive predictive value (PPV) of a single code for PsA has been reported to be over 90% in another electronic medical record database. The use of diagnostic codes plus disease-modifying antirheumatic drug data definitions only slightly and significantly improved the specificity for each diagnosis, but at the cost of a dramatic reduction in sensitivity. Therefore, we defined PsA based on its Read diagnostic code in this study.

Assessment of exposure and covariates

Demographics, lifestyle factors and history of trauma were collected from the database before the index date. THIN lifestyle exposure variables have been collected prospectively and successfully used in previous analyses by confirming anticipated associations such as those among alcohol, BMI and gout; smoking and lung cancer; smoking, obesity and myocardial infarction; and alcohol and paroxysmal atrial fibrillation. Our exposure of interest was BMI, defined as the patient’s body mass in kilograms divided by the square of his or her height in metres. We analysed the impact of the first recorded BMI after all these eligibility criteria were met (eg, the first BMI recorded after psoriasis diagnosis in our primary study cohort). We repeated our analysis using updated BMI as a time-varying exposure, our analysis limited to patients with incident psoriasis (n=27 980). This allowed us to examine the potential impact of psoriasis duration on varying risks of PsA. For all RRs, we calculated 95% CIs. All p values are two-sided. All statistical analyses were performed using SAS software, V.9.2 (SAS Institute, Cary, North Carolina, USA).

We repeated our analysis in the THIN population by additionally including those without psoriasis status (n=1 950 744). In this analysis, we examined the impact of including the diagnosis of psoriasis in the model, as BMI is a known risk factor for psoriasis and, thus, can act as a potential causal intermediate. We also repeated the analysis limited to patients with incident psoriasis (n=27 980). This allowed us to examine the potential impact of psoriasis duration on varying risks of PsA. For all RRs, we calculated 95% CIs. All p values are two-sided. All statistical analyses were performed using SAS software, V.9.2 (SAS Institute, Cary, North Carolina, USA).

RESULTS

Our primary analysis included 75 955 psoriasis patients for a combined follow-up time of 368 302 person-years, during which 976 cases of incident PsA were diagnosed. The incidence rate of PsA in this population was 26.5 per 10 000 person-years. Table 1 summarises the baseline characteristics of the study cohort according to BMI.

Values are percentages unless otherwise noted.

There were fewer men overall, which was most notable in the highest and lowest BMI categories. Lower BMI categories tended to have more current smokers and fewer past smokers. Other variables were similarly distributed across BMI categories.

Higher categories of BMI were associated with an increased incidence of PsA (p for trend <0.001) (table 2 and figure 1). Compared with psoriasis patients with BMIs <25, those with BMIs of 25–29.9, 30.0–34.9 and ≥35.0 had age- and sex-adjusted RRs of 1.1, 1.24 and 1.52, respectively (p for trend <0.001). After adjusting for age, sex, smoking, alcohol consumption and history of trauma, these RRs were slightly attenuated but remained significant (p for trend <0.001) (table 2). We repeated our analysis using updated BMI as a time-varying exposure, our results did not change materially (p for trend <0.001).

We repeated the calculation by additionally including those without psoriasis status (n=1 950 744), higher categories of BMI were associated with an increased risk of PsA (p for trend <0.001) (table 3 and figure 2). Compared with individuals with BMIs <25, those with BMIs of 25–29.9, 30.0–34.9 and ≥35.0 had age- and sex-adjusted RRs of 1.17, 1.60 and

Our primary objective was to evaluate the association between BMI and the risk of PsA among patients with psoriasis from the general population. We found that increasing BMI among patients with psoriasis was associated with an increasing risk of PsA, demonstrating a dose-response relation. These associations were independent of other potential confounders such as age, sex, trauma, smoking and alcohol intake. These data provide the first general population-based evidence that obesity is associated with an increased risk of developing PsA among psoriasis patients as well as in the general population.

A recent cross-sectional study reported that PsA patients have a higher BMI than psoriasis patients. Another study based on psoriasis patients recruited consecutively from the dermatology clinic of the University of Utah reported an independent association with recalled BMI at age 18, but no such associations with current BMI among psoriasis patients. However, as the current BMI data in that study were measured after the study recruitment when PsA status was determined, they reflect adiposity levels after the onset of PsA (as opposed to BMI before the onset of PsA). Furthermore, because the recalled BMI data at age 18 do not take into account BMI changes that occurred from age 18 leading up to and following the development and diagnosis of psoriasis, its utility for predicting the future risk of PsA based on adiposity status of psoriasis patients is unclear. Our results filled this knowledge gap by examining the relation between BMI after psoriasis diagnosis (and before PsA onset) and the risk of PsA.

Potential explanations for this increased risk for PsA among obese psoriasis patients include the inflammatory load associated with adiposity, contributing further to that associated with their underlying psoriatic condition. Obesity is associated with an overproduction of inflammatory cytokines including IL-1, IL-6, IL-8 and tumour necrosis factor α, and there is a correlation between the level of adiposity and the measured peripheral levels of associated inflammatory cytokines. Randomised trial data showing beneficial additive effects of weight loss and case reports of psoriasis clearing with reducing obesity suggest that this inflammatory milieu provided by the overabundance of adipose tissue may be important in the pathogenesis of psoriatic conditions. An alternative speculation for the increased risk observed here could be that mechanical wear, secondary to obesity, could trigger PsA in load-bearing joints, with subsequent spread of the inflammatory arthritis to other joints.

Our findings may have practical implications for the management of psoriasis patients, as PsA is common in these patients, affecting about 6–10% of psoriasis patients overall. Thus, a modifiable risk factor, such as obesity, requires a relatively small number needed to treat among psoriasis patients compared with the general population context with a lower background risk of developing PsA. Although a randomised trial would be needed to definitively establish the usefulness of weight reduction in reducing the risk of PsA, this type of study may be difficult to perform, given the large number of psoriasis patients and trial durations necessary for sufficient cases of PsA to occur, the high costs and anticipated ethical issues. Meanwhile, as weight reduction in obese individuals has multiple health benefits, including reduced cardiovascular and mortality risks, these benefits appear all the more relevant for obese psoriasis patients to help prevent psoriasis patients recruited consecutively from the dermatology clinic of the University of Utah reported an independent association with recalled BMI at age 18, but no such associations with current BMI among psoriasis patients. However, as the current BMI data in that study were measured after the study recruitment when PsA status was determined, they reflect adiposity levels after the onset of PsA (as opposed to BMI before the onset of PsA). their excess risk of PsA along with co-morbidity and mortality complications.

The strengths and limitations of our study deserve comment. This study was performed using a large UK general practice database; therefore, findings are likely to be applicable to the general population. While the designs of previous studies on the topic made it difficult to establish the temporal relations between BMI and the risk of PsA, our study design, including the time-point of exposure measurement and the incident case outcome analysis, enabled us to establish temporal relations between these factors.13 14 Uncertainty surrounding diagnostic accuracy is a potential concern in studies that identify cases from administrative databases. As is well reflected in the medical records used for patients’ care, thus the overall accumulative databases. However, our databases are actually electronic potential concern in studies that identify cases from administrative databases. Unlike rheumatoid arthritis (RA), this is likely because both PsA and Psoriasis belong to this group of ‘specific’ diagnoses, likely due to factors.13 14 Uncertainty surrounding diagnostic accuracy is a potential concern in studies that identify cases from administrative databases. Therefore, findings are likely to be applicable to the general population. While the designs of previous studies on the topic made it difficult to establish the temporal relations between BMI and the risk of PsA, our study design, including the time-point of exposure measurement and the incident case outcome analysis, enabled us to establish temporal relations between these factors.13 14 Uncertainty surrounding diagnostic accuracy is a potential concern in studies that identify cases from administrative databases. However, our databases are actually electronic medical records used for patients’ care, thus the overall accuracy is expected to be higher, as reflected in many validation studies of important outcomes.16-29 As is well reflected in the high PPV estimates for a psoriasis code in THIN (90%),16 and for a PsA code in another electronic medical record database (>90%),17 our cohort definition (psoriasis patients) and outcome (PsA) belong to this group of ‘specific’ diagnoses, likely due to the characteristic skin lesions of psoriasis and the clinical context in which PsA is diagnosed. PsA is among those specific diagnoses that are usually first made or confirmed by rheumatologists (unlike rheumatoid arthritis (RA)).17 This is likely because both referring physicians and patients are not as familiar with this diagnosis as they are with other common types of arthritis (eg, RA or osteoarthritis) and there are no widely available blood tests that flag the diagnosis of PsA (eg, rheumatoid factor or anti-cyclic citrullinated protein for RA).

In conclusion, this general population study suggests that obesity is associated with an increased risk of incident PsA and supports the importance of weight reduction among psoriasis patients who often suffer from the metabolic syndrome and obesity.
