REITER'S SYNDROME IN FATHER AND SON

BY

K. R. GOUGH

Department of Medicine, Bristol Royal Infirmary

Reiter's syndrome consists of a non-specific urethritis, conjunctivitis, polyarthritis, and a number of less constant features (Reiter, 1916).

The cause of the urethritis is unknown but it is commonly regarded by venereologists as an infective condition of venereal origin. Although a yearly average of more than 12,000 cases of non-specific urethritis have been reported to the Ministry of Health by Venereal Disease Clinics since 1951, only a small proportion (3 to 4 per cent.) develop the features of Reiter's syndrome.

It has been suggested that hereditary predisposition may perhaps explain why some patients with non-specific urethritis develop Reiter's syndrome (Laird, 1958). Some support for this theory is afforded by this paper which reports the occurrence of the syndrome in father and son.

Case Reports

Case 1, a schoolboy, aged 15, was admitted to another hospital in May, 1957, with a history of pain and swelling of the knees and ankles. An initial diagnosis of acute rheumatism was made and treatment was started with aspirin. He continued to run a pyrexia (99-100° F.), but the erythrocyte sedimentation rate fell from 100 mm. in 1 hour (Wintrobe) in June to 8 mm. at the end of July. It then became clear that he had Reiter's syndrome as he developed a high fever and severe bilateral conjunctivitis. At this time he had had no urethral discharge and denied any form of sexual exposure. One week later pain and swelling developed in the left ankle, the first right metacarpophalangeal joint, and both knees, and the typical skin lesions of keratoderma blennorrhagica were noted on the soles of both feet (Figure, opposite).

Laboratory Investigations.—Hb 84 per cent., blood film normal, white blood cells 5,500/c.mm.

Erythrocyte sedimentation rate 37 mm. in 1 hour (Wintrobe).

E. coli were identified on culture of a urethral smear, but no pleuropneumonia-like organisms were demonstrated.

X rays showed osteoporosis of the right wrist and

thumb. Sub-periosteal new bone was present along the base of the proximal phalanx of the right thumb and the first metacarpal bone. Later views demonstrated consolidation of the periosteal new bone and a marginal erosion on the lateral aspect of the first right metacarpal.

Progress.—The condition responded to fever therapy but not to salicylates. One year later (May, 1958) he developed an acute recurrence with arthritis and keratoderma, this time accompanied by non-specific urethritis, although again there was no history of venereal exposure. X rays showed osteoporosis of the ends of both tibiae and fibulae, with an erosion on the medial aspect of the left medial malleolus. Irregularities were noted at the sites of the ligamentous attachments of both tali and calcanei.

He responded again to fever therapy and was fit for discharge in June, 1958. When seen in September, 1958, he complained of some tenderness of the soles of both feet and some low back pain, but was able to continue his apprenticeship as a joiner. He has since been lost to follow up.

Case 2, a 41-year-old salesman, father of Case 1, was first seen in the Out-Patients' Department on February 27, 1958, complaining of episodes of pain and swelling of the ankles over the previous 2 years, and a recent, more severe attack involving the lumbar and cervical spine, both shoulders, and both wrists. These symptoms were accompanied by a constitutional illness with loss of weight and general malaise and had persisted for several weeks. There was a history of a post-coital urethral discharge 5 years previously while serving in the armed forces in India, and this had recurred several times during the previous 2 years. The patient claimed that investigations carried out in India at the time of the initial discharge were negative for both syphilis and gonorrhoea. He had never had conjunctivitis or iritis.

Examination.—He looked pale and ill, with a sub-normal body temperature (97.4° F.). Movements of the cervical spine were painful, so that he held his neck slightly flexed and rigid. Movements of lumbar spine were also limited by pain, but no deformity was present. Both ankles were swollen and painful, and effusions were present in both knee joints. The hands and wrists were clinically normal.

Figure.—Plantar skin lesions typical of keratoderma blennorrhagica in Case 1.

Laboratory Investigations.—Hb 72 per cent. (10.7 g./100 ml.), blood film normal, white blood cells 7,300/c.mm.

Erythrocyte sedimentation rate 55 mm. in 1 hour (Wintrobe).

Mid-stream urine showed no albumin. Centrifuged deposit revealed very scanty white cells and culture was sterile. No pleuropneumonia-like organisms were demonstrated.

The Wassermann reaction and differential agglutination test were negative. Agglutination tests were negative for *Brucella* and *Shigella* organisms.

The serum uric acid was 4.2 mg./100 ml.

X rays of the chest and sacro-iliac joints were normal.

On the plantar aspect of both calcanei there was a small area of cortical absorption at the insertion of the plantar aponeurosis.

Treatment.—Initial treatment with large doses of aspirin was unsuccessful and a course of fever therapy (T.A.B. intravenous injections) produced no significant improvement. Prednisone 10 mg. twice daily was then started, and this produced an immediate improvement in the pain, and increased the mobility of all the affected joints. The dose was reduced to 5 mg. three times daily, and on August 11, 1958, he was discharged home. Since then he has ignored requests to return to the Out-Patients' Department for follow-up.

Discussion

The association of conjunctivitis, relapsing polyarthritis, non-specific urethritis, and keratoderma blennorrhagica leaves little doubt that Case 1 had Reiter's syndrome. It is likely that the father, Case 2, also suffered from the same condition. The pattern of joint involvement in both cases is typical of that seen in Reiter's syndrome. In fact, the diagnosis in the father was first suggested by the similarity of the joint involvement seen one year previously in the son. The urethritis occurring in the son was presumably not venereal in origin since he persistently denied sexual exposure, but it is possible that he contracted the infection from his father who had had a recurrent urethral discharge for a year or so before the onset of symptoms in the son.

Hereditary disposition is said to occur in a wide variety of rheumatic disorders. Rheumatoid arthritis occurs more often in the families of patients than in the families of matched controls (Hersh, Stecher, Solomon, Wolpaw, and Hauser, 1950). West (1949) concluded that the familial incidence of ankylosing spondylitis was greater than might be

expected on the grounds of chance alone. The familial incidence of gout is well established (Stecher, Hersh, and Solomon, 1949), and a familial tendency has been claimed in rheumatic fever (Stevenson and Cheeseman, 1956).

Some evidence exists that there may also be a familial predisposition to Reiter's syndrome. Csonka (1958) reported the condition occurring in two brothers, and Morton (1958) in first cousins. A full-scale investigation of the families of patients with Reiter's syndrome has not been reported. The two cases described in this paper lend some support to the theory that a familio-hereditary factor operates.

An interesting analogy between rheumatic fever and Reiter's syndrome has been proposed by Laird (1958), who postulated that the polyarthritis of Reiter's syndrome might arise from sensitization of the tissues following infection in the genito-urinary or intestinal tracts, much as acute rheumatism follows a streptococcal sore throat. Just as only a small proportion of patients with streptococcal sore throats develop acute rheumatism, only a small proportion of patients with non-specific urethritis develop Reiter's syndrome. Hereditary predisposition may be one of the factors determining which patients develop the polyarthritis, conjunctivitis, and the less common features of the syndrome.

Summary

It has been suggested that hereditary predisposition may perhaps explain why some patients with non-specific urethritis develop Reiter's syndrome. Some support for this theory is afforded

by this paper which reports the occurrence of the syndrome in father and son.

I wish to express my thanks to Professor C. Bruce Perry for permission to publish details of both cases and for his help with the manuscript.

Syndrôme de Reiter chez père et fils

RÉSUMÉ

Il existe une hypothèse selon laquelle une prédisposition héréditaire expliquerait le fait que certains malades atteints d'une uréthrite non-spécifique développent le syndrome de Reiter. Cet article rapportant l'occurrence de ce syndrome chez père et fils vient à l'appui de cette théorie.

Síndrome de Reiter en padre e hijo

SUMARIO

Se había sugerido que una predisposición hereditaria pudiera quizás explicar por qué ciertos enfermos con uretritis non-específica desarrollan el síndrome de Reiter. En este artículo, en apoyo de la dicha teoría, se relata la ocurrencia de este síndrome en padre e hijo.
