Effect of dextran on the reaction between rheumatoid factor and human gamma globulin

A. E. FINKELSTEIN, G. ISLER, AND I. ORESKES

From the Rheumatology Research Department, Fundación CIMAE (Centro de Investigaciones Médicas Albert Einstein), Buenos Aires, Argentina, and the Mount Sinai School of Medicine of the City University of New York, New York, N.Y. 10029, U.S.A.

The present study on the effect of polysaccharide dextran on the interaction of human gamma globulin (IgG) with rheumatoid factor (RF), was initiated by Finkelstein, Kwok, and Bayles (1960) after a clinical observation that intravenous infusion of a 6 g. per cent. saline solution of dextran, 75,000 MW in patients with active rheumatoid arthritis induces marked exacerbation of disease activity. This disease activity was accompanied by an increase of intravascular erythrocyte aggregation as evidenced by stereomicroscopic observation of the blood flow in the vessels of the bulbar conjunctiva (Finkelstein, Kwok, Hall, and Bayles, 1961).

We have reported previously that dextran, when added to a rheumatoid serum, induces a precipitate which contains all RF activity (Finkelstein and others, 1960). It has also been shown that immunoglobulin can be eluted from red cell surfaces with solution of dextran. The protein eluted from red cells of patients with rheumatoid arthritis (RA) and other diseases were shown to contain antiIgG activity (Finkelstein and others, 1960; Finkelstein and others, 1961; Blodgett, Hill, Mayne, and Owen, 1963; Finkelstein, Woerner, Smith, Bayles, and Levine, 1963).

In the present paper it will be demonstrated that, in the presence of dextran, both the agglutination of IgG-coated latex particles by sera containing RF and the amount of IgG precipitates are increased. Evidence is presented which supports the concept that dextran blocks the autoinhibitory IgG activity present in the patient's own serum, as well as the inhibitory activity of the pooled human IgG present in test systems, with consequent enhancement of the immunological interactions.

Material and methods

Dextran of various molecular weights was obtained from Abbot Laboratories, Detroit, Mich. Unless otherwise

specified, dextran of 75,000 MW was used, dissolved in water or saline (0.15 M NaCl). Aggregates of IgG were prepared by sodium sulphate precipitation according to the method of Christian (1958). The standard method of Singer and Plotz (1956) was employed for the latex-fixation test (FIILP), and for the sensitized sheep cell test the method of Rose, Ragan, Pearce, and Lipman (1948) was used.

PRECIPITIN STUDIES

(1) Whole rheumatoid factor serum was diluted 1:8 with 6 g per cent. solution of dextran, and as a control the same serum was diluted 1:8 in saline, without dextran. To 0.2 ml. of the diluted serum was added increasing amounts of aggregated IgG and the mixture was brought to a final volume 0.6 ml. with saline. The tubes were allowed to stand at room temperature for 1 hr, and then at 4°C. for 24 hrs. The resulting precipitates were washed twice with ice cold saline at 4°C., and the supernatant fluid decanted after centrifugation at 1,400 G for 15 min. The precipitates were dissolved in 0.1 N NaOH, and protein concentration measured by the method of Lowry, Rosebrough, Farr, and Randall (1951).

(2) In another type of precipitin experiment, 0.25 ml. of rheumatoid factor serum was mixed with constant amounts of dextran solution and increasing amounts of aggregated IgG. The tubes were all brought to a final volume of 6 ml. with phosphate buffer, pH 8.0 and incubated for 7 days at 4°C. The precipitates were washed three times with ice cold saline and analysed for nitrogen by the Micro Kjeldhal technique, and both supernatants and dissolved precipitates assayed for RF activity.

Immunoelectrophoresis in agar gel was done by the technique of Scheidegger (1955).

INHIBITION EXPERIMENTS

Euglobulin inhibition

Euglobulin from pooled non-rheumatoid normal serum was obtained by dialysis against dilute phosphate citrate buffer at pH 5.8 at 4°C. for 48 hrs (Ziff, 1957). The precipitate was washed with cold buffer at pH 5.8 and redissolved with neutral buffer to original volume. The capacity of

this material to inhibit the agglutination in the FIILP test by rheumatoid serum was determined by the technique of Hall, Mednis, and Bayles, (1958).

Block titration procedure

This technique employing human IgG coated tanned sheep cells (TSC) at six different concentrations, 0.125, 0.25, 0.50, 1.0, 1.5, and 2.0 vol per cent., was performed according to the method of Oreskes and Plotz (1965) and Oreskes and Shore (1966). Equal volumes of test serum and 0.15 NaCl of various concentrations of dextran or glucose were mixed and incubated at 37°C. for 1 hr before titration.

Results

In the following experiments the effect of dextran on agglutination, precipitation, and inhibition of agglutination in the rheumatoid factor-IgG immunoglobulin system have been studied.

Table I demonstrates that the presence of dextran enhances both the degree of agglutination and the titre of RF in the FIILP test procedure. To study further this phenomenon, equal volumes of various concentrations of dextran solution and RF serum were mixed and incubated at room temperature for 20 minutes. Precipitates were centrifuged and redissolved in glycine buffer, pH 8.2, and both supernatants and precipitate solutions tested for RF. As can be seen in Table II, more complete precipitation of rheumatoid factors was achieved with an aqueous solution of dextran. Identical results were obtained with the sensitized sheep cell test and the latex-fixation test in following the presence or absence of RF activity in precipitates or supernatants.

The experiment described in Table II was repeated with dextrans of MW 10,000, 15,000, 25,000, 188,000, and 226,000. In all cases the degree of completeness

It has been established, then, that dextran enhances agglutination of FIILP by rheumatoid serum, and also enhances the precipitation of RF in precipitin studies. To test the possibility that dextran blocks the inhibitory effect of IgG upon rheumatoid activity, we studied the effect of dextran on inhibition of FIILP agglutination by the euglobulin fraction (Hall and others, 1958). Table IV shows that normal euglobulin fraction, treated with increasing amounts of dextran, progressively loses its capacity to inhibit agglutination of FIILP by a rheumatoid factor serum.

The blocking effect of dextran upon the auto-inhibitory property of human serum IgG was further explored by a block titration procedure (Oreskes and Plotz, 1965; Oreskes and Shore, 1966).

Fig. 4 demonstrates the dependence of TSC titre for two RF sera on the concentration of IgG-coated tanned sheep cells employed. Titres were inversely proportional to cell concentration, and in general double logarithmic plots of titre as a function of cell concentration were linear. With one serum it may be seen that a twofold increase in cell concentration resulted in a two fold decrease in titre. This yielded a 'normal' slope value for the linear plot of -1.0 .

FIG. 4 Relationship between agglutination titres and concentrations of tanned coated cells in two RF sera

Table IV Effect of dextran on euglobulin inhibition of IgG coated latex particle agglutination by rheumatoid factor serum

Reaction mixture	Agglutination
RF serum only	3+
RF serum + normal euglobulin	—
RF serum + normal euglobulin + dextran	—
0.1 per cent.	1+
0.5 per cent.	2+
1.0 per cent.	3+
4.0 per cent.	3+
8.0 per cent.	4+
16.0 per cent.	4+
20.0 per cent.	4+

However, in the majority of RF sera tested, slope values of greater than -1.0 were obtained with values ranging up to -2.3 (Oreskes and Plotz, 1965). In other words, most RF sera exhibited an enhanced decrease in titre with increasing cell concentration. An example of such a 'high slope' serum is shown in Fig. 4. Addition of heat-aggregated human IgG immunoglobulin to a normal slope serum resulted in an increase in slope as shown in Fig. 5. This increase in slope value demonstrated an inhibitory effect of the added aggregated IgG on titre (Oreskes and Plotz, 1965; Oreskes and Shore, 1966).

FIG. 5 Effect of aggregated human IgG immunoglobulin on agglutination titres and slope of RF serum. Aggregated γ G: 10 mg. per cent. solution of human γ G immunoglobulin in 0.15 M NaCl heated at 63°C . for 60 min.; then 10 μ l. (0.10 mg γ G) added to 1.0 ml. test serum and incubated for 60 min. at 37°C . before titration

To test the effect of dextran on autoinhibition, this polysaccharide was added to a high slope serum (slope = -1.5). The results are shown in Fig. 6.

In the presence of dextran, titres increased, particularly at higher tanned cell concentrations, and consequently the slope value was decreased, in this instance to a 'normal' value of -1.0 . Addition

copyright.

FIG. 6 Effects of dextran on agglutination titres and slope of a RF serum

of dextran to a serum of 'normal' -1.0 slope was without effect on the slope or on individual titres.

These effects are summarized in Table V. A RF serum when tested alone yielded a slope of -1.5 . Addition of dextran to this serum lowered the slope to -1.2 . Addition of aggregated IgG in the absence of dextran raised the slope to -1.8 . Finally, addition of both dextran and aggregated IgG resulted in a lowered slope to a near 'normal' value of -1.1 . These results confirmed that the added dextran counteracted the inhibitory effects of autologous IgG as well as of added aggregated IgG.

The enhancing effect of dextran on agglutination titres and slopes was not a consequence of interactions between dextran and the IgG-coated tanned sheep cells used. Six different sera were titrated with tanned cells prepared as indicated (Oreskes and Plotz, 1965), and with cells additionally exposed to dextran before use. There was no difference in either agglutination titres or slopes obtained with the two types of cells.

In other experiments, addition to RF sera of 0.15 M NaCl or glucose in varying concentrations up to 20 g. per cent. was without effect on either titres or slopes.

Finally, Fig. 7 shows immunoelectrophoresis in agar gel of aliquots of IgG dissolved in saline (SIgG), and in a 2 per cent. solution of dextran (DIgG)

against a rabbit antihuman IgG antisera. It can be seen that a larger thicker immunoprecipitin arch is elicited with the IgG dissolved in dextran as compared with the same amount of IgG dissolved in saline.

FIG. 7 Dextran enhancement of IgG precipitation by antiIgG antisera in immunoelectrophoresis

Discussion

In this study it has been demonstrated that solutions of dextran enhance the agglutination of latex particles coated with IgG by rheumatoid factor serum and enhance the precipitation of IgG-RF immune complexes. The effect obtained when dextran is added to euglobulin suggests binding of inhibitory IgG by this polysaccharide. Similarly, the presence of dextran diminishes the inhibitory capacity of autologous IgG present in the patient's serum, as evidenced by the slope lowering effect (Table V).

Dextran has also been shown to increase agglutination of antibodies in other immune systems. An antiA serum with an agglutination titre of 256 in saline solution showed a titre of 4,096 in medium containing 3 g. per cent. dextran (Marston, 1954).

Although the work of Hellsing (1969a, b) points to the fact that dextran decreases the solubility of immune complexes because of steric exclusion, in the dextran IgG rheumatoid factor system both steric exclusion and a blockade of inhibitory IgG might be the mechanism for the enhancement of the RF-IgG interaction.

Table V Effect of dextran and aggregated IgG immunoglobulin on TSC titres and slopes of a rheumatoid factor serum

System	TSC Titre*	Slope
Serum alone	1:5120	-1.5
Serum + dextran †	1:5120	-1.2
Serum + aggregated γ G ‡	1:2560	-1.8
Serum + aggregated γ G + dextran	1:2560	-1.1

* Standard TSC titre obtained with 0.25 per cent. cells.

† Dextran concentration 30 g. per cent.

‡ Aggregated IgG: human FII heated at 63°C. for 30 min.

For further discussion of the probable mechanisms of dextran participation in the immunological interactions, we refer the reader to Ceska's explanation of the effect of dextran upon insulin-anti-insulin precipitates (Ceska, 1968).

An important point arising from this work the question whether the blocking effect on autoinhibitory IgG by polysaccharides in rheumatoid arthritis induces increased precipitation of immune complexes *in vivo*, which play a role in the inflammatory reactions. This could be the mechanism of exacerbation of rheumatoid disease activity by dextran infusion described by Finkelstein and others, (1960). The adverse effect of intravenous iron-dextran in rheumatoid arthritis recently reported may be due to the same mechanism (Reddy and Lewis, 1969).

These observations together with work in progress, contraindicate infusion of solutions of dextran into patients with active rheumatoid disease, hypergammaglobulinaemia, and high rheumatoid factor titre, without simultaneous administration of steroids.

The data here presented are consistent with the concept that rheumatoid disease activity is mediated by IgG-RF immune complexes, and suggests that exacerbations of rheumatoid inflammation may be induced or enhanced by circulating polysaccharides.

Summary

Studies of the effect of dextran on the interaction of rheumatoid factor (RF) with human IgG have demonstrated that, in the presence of dextran, both the agglutination of IgG-coated latex particles by sera containing RF and the formation of immune precipitates are increased. Evidence is presented which supports the concept that the increment is due to the binding by dextran of inhibitory IgG present in the test system, and binding of autoinhibitory IgG in the patient's own serum. These data, plus earlier observations that in active rheumatoid arthritis infusion of dextran induces subjective and objective exacerbation of rheumatoid inflammation, suggest that rheumatoid inflammation is mediated by enhancement of intravascular immune precipitation by circulating polysaccharides of diverse origin.

We are indebted to Dr. Frank Gardner for his continuous interest and stimulus, to Drs. Arthur P. Hall and Ralph Heimer for their aid and advice, and to Dr. Theodore B. Bayles, Robert B. Brigham Hospital, Harvard Medical School, in whose laboratory this work was begun. We are grateful to Dr. Jose Zelasco, Head of the Department of Medicine, Fernández Hospital of Buenos Aires, for the clinical material, and to Dr. Leonor Martinez and Selva García, B.Sc., for assistance in some of the experimental work.
