SUMMARY Two pairs of sibs with definite rheumatoid arthritis responded in a remarkably similar way to parenteral gold therapy, in terms of both toxicity and efficacy. Both pairs proved to be HLA identical. One of the pairs possessed the HLA antigens B8 and DR3, which have been associated with both drug toxicity and excellent clinical response. The other pair did not possess either of these antigens, suggesting that the reaction to gold therapy in patients with rheumatoid arthritis may be determined by other HLA or genetic factors coded for by chromosome 6, or both.

Key words: HLA antigens.

Parenteral gold is still a cornerstone of drug treatment of rheumatoid arthritis (RA). Disadvantages of the drug are its frequent toxicity and its ineffectiveness in some patients. Recently, associations with certain HLA antigens have indicated that genetic factors have a role in both gold toxicity and effectiveness.¹⁻⁴ HLA antigens involved include B8 and DR3 in gold toxicity and DR3 in predicting excellent response to the drug.¹⁻³ Another study found a relation between the absence of antigen A3 and the simultaneous presence of antigen DR4 and poor response to parenteral gold.⁴

In the present report we describe two pairs of sibs with rheumatoid arthritis who responded in a remarkably similar way to parenteral gold therapy, in terms of both toxicity and clinical response, one of the sib pairs doing so during two subsequent courses of parenteral gold. Tissue typing showed that both pairs of sibs were HLA identical; whereas one pair of sibs was HLA-B8 and DR3 positive, the other one did not possess HLA antigens known to be associated with toxicity or clinical response. This observation suggests that other HLA antigens or genetic factors coded for by chromosome 6, or both

may have a role in the response to parenteral gold in patients with rheumatoid arthritis.

Patients and methods

In a large study on families with multiple cases of rheumatoid arthritis we detected two sib pairs with definite rheumatoid arthritis according to the revised American Rheumatism Association diagnostic criteria,⁵ who responded in a remarkably similar way to parenteral gold therapy with aurothioglucose. Toxicity was monitored by regular questionnaire, physical examination, blood counts, and urine analysis. Response to gold therapy was evaluated according to a modification of a recently published scoring system for patients with rheumatoid arthritis.^{3,6} Parameters used in this evaluation are the duration of morning stiffness, observer assessment, haemoglobin, and erythrocyte sedimentation rate (ESR). HLA typing was done with standard National Institute of Health microlymphocytotoxicity techniques for HLA-A, B, C, and DR antigens. Sera were partly of local origin, all sera being standardised against the 8th and 9th International Histocompatibility Workshop sera.

Case reports

All four patients had a symmetrical polyarthritis.

Accepted for publication 5 June 1986.

Patient characteristics and data on the reaction to parenteral gold are presented in Tables 1 and 2 respectively.

SIB PAIR I (TWO SISTERS)

Patient No 1 developed rheumatoid arthritis at the age of 53 and failed to respond to non-steroidal anti-inflammatory drugs (NSAIDs). At the age of 54 treatment with aurothioglucose was started. After 250 mg of parenteral gold she developed a rash necessitating stopping the treatment. At this time there were only minimal signs of arthritis. The rash disappeared within one month. Patient No 2, her elder sister, developed rheumatoid arthritis at the

age of 54. Treatment with NSAIDs and hydroxychloroquine was not successful. At the age of 58 treatment with aurothioglucose was instituted. After 850 mg of the drug, given over a period of three months, she developed a maculopapular rash and treatment had to be stopped. Thereafter, the rash gradually disappeared. At the time of the rash her rheumatoid arthritis was quiescent.

SIB PAIR II (BROTHER AND SISTER)

Patient No 3 developed rheumatoid arthritis at the age of 53. At first he had been treated with NSAIDs and hydroxychloroquine, which was initially effective but subsequently did not control disease

activity. At the age of 58 years gold therapy was instituted. After four months he developed dermatitis and a slight stomatitis, and gold was stopped. At that time there was no evident disease activity. Approximately five and a half years later gold was reinstituted because of a disease flare. This treatment had to be stopped after a cumulative dose of 500 mg because of a rash.

Clinical response was good, though some residual swelling of the joints was present. Patient No 4, his elder sister, developed rheumatoid arthritis at the age of 71. She was initially treated with NSAIDs and hydroxychloroquine, without clinical effect. At the age of 72 gold therapy was started; after four months of treatment there were no signs of active arthritis. At the cumulative dose of 1100 mg she had a moderately severe dermatitis, and gold was stopped. There were no signs of disease activity at that time. Because of a flare, gold was reinstituted one and a half years later. After three months of therapy the disease was in remission, but after a total dose of 800 mg (over nine months) she developed dermatitis again, necessitating stopping the treatment. At that stage there was evidence of only slight disease activity.

Discussion

This report shows remarkably similar reactions to parenteral gold therapy in two sib pairs, in terms of both toxicity and favourable clinical response to the drug. Tissue typing showed that the sib pairs were HLA identical. Toxicity on parenteral gold therapy has been found in some studies to be associated with certain HLA antigens, namely HLA-B8 and DR3.^{2-7,10} These associations were predominantly found for gold induced proteinuria^{7,8} and thrombocytopenia.^{9,10} Interestingly, an association between the most frequent side effect, i.e., skin rash, and HLA antigens has been found in only a few studies.^{2,11,12} Bardin *et al* found an association with the haplotype A1 Cw7 B8 DR3,¹¹ and our group has recently reported an association with HLA-B8 and DR3.¹² It should be stressed, however, that other groups have been unable to find associations between HLA antigens and gold toxicity.^{13,14}

The patients in these two sibships developed the same pattern of toxicity and in addition, showed the same favourable clinical response to the drug. One of the sib pairs possessed the haplotype HLA-B8 and DR3; antigens that have been associated with both gold toxicity^{1,2,7-11} and excellent clinical re-

sponse.^{3,12} The other sib pair, however, did not possess these antigens. Both patients of the latter sib pair received two courses of gold and on each occasion reacted identically to this treatment. This observation suggests that other genetic factors associated with chromosome 6 may have a role in the reaction to parenteral gold therapy.

Although suggestive, the present data are anecdotal and need to be confirmed by more extensive studies. There is, however, accumulating evidence that genetic factors have a role in the way patients react to antirheumatic drugs, in terms of both side effects and efficacy.
