LOW FREQUENCY OF CHRONIC BIOLOGICAL FALSE POSITIVE REACTORS TO SEROLOGICAL TESTS FOR SYphilis IN RHEUMATOID ARTHRITIS AND ANKYLOSING SPONDYLITIS

From the State Serum Institute, Helsinki, Rheumatism Foundation Hospital, Heinola, and Department of Hygiene, University of Helsinki, Finland

In the so-called collagen diseases there is considerable overlapping of both clinical signs and serological phenomena. Elevated serum globulins, L.E.-cells, rheumatoid factors, and chronic biological false positive (CBFP) serological reactions for syphilis have been observed both in rheumatoid arthritis (RA) and in systemic lupus erythematosus (SLE). The frequency of RA among CBFP-reactors has been estimated at about 10 per cent. or even less (Wuepper, Bodily, and Tuffanelli, 1966; Putkonen, Jokinen, Lassus, and Mustakallio, 1967; Miller, Brodey, and Hill, 1957). On the other hand, the frequency of CBFP-reactors among patients with RA has been reported to be in the range of 5 to 11·6 per cent. (Moore and Mohr, 1952; Waldenström and Winblad, 1958; Kivelitz, Goslings, Schuit, and Hjimans, 1956). These figures seem high considering the common occurrence of rheumatoid arthritis (Kellgren, 1966) and the low percentage of positive serological tests for syphilis in unselected cases.

We have therefore studied the occurrence of CBFP reactions in a large series of patients treated at a specialized rheumatism hospital and diagnosed according to uniform criteria.

Material and Methods

The present series is based on 14,676 patients treated during the years 1952-1966 at the Rheumatism Foundation Hospital, Heinola. The majority had either rheumatoid arthritis (about 10,500) or ankylosing spondylitis (about 400), systemic lupus erythematosus was diagnosed in about 150, and the others had degenerative joint disease, rheumatic fever, or some other joint disease. The average age was about 40 years, less than 10 per cent. of the total being over 60 years of age.

Sera from all patients were screened by the VDRL test. In 1952-1963 the screening was performed at the Rheumatism Foundation Hospital and the sera giving positive reactions were re-tested at the State Serum Institute, Helsinki. From 1963 onwards, the screening was performed at the State Serum Institute.

The TPI test was available from 1961 and the FTA-ABS test from 1966. In 1963 the patients with positive serology were re-examined. Sera were obtained from about half of the positive cases and subjected to the TPI test. A second re-examination was carried out in 1967 to control the cases treated from 1963 to 1966; these were examined by both the TPI and FTA-ABS tests.

The TPI test was done by the technique of Nelson and Mayer (1949) and Nelson and Diesendruck (1951), with small modifications. The FTA-ABS test was performed according to the provisional technique published in 1965 by the Venereal Disease Laboratory of the Communicable Disease Center, Atlanta, Georgia. The VDRL test was performed according to standard techniques, using Sitolipin as an antigen (S.T.S. Manual, 1959; Uroma and Tommila, 1951).

Results

The VDRL test was positive in 97 patients, 78 of whom had rheumatoid arthritis, four ankylosing spondylitis, five systemic lupus erythematosus, and ten other joint conditions.

Clinical information about syphilis was obtained from 36 of the 82 patients with RA or AS. This information, together with the results of the treponemal antibody tests, is presented in the Table. The results of these tests were fairly similar. In only one case was the TPI test negative and the FTA-ABS test positive; this patient had congenital syphilis.

For the other 46 patients with rheumatoid arthritis or ankylosing spondylitis there was no information about syphilis; 24 sera were examined by treponemal antibody tests, and the results are presented in the Figure. In eighteen of the 46 cases the positive VDRL result was of a transient nature. The patients for which treponemal antibody tests were performed are shown separately in the Figure. The probable number of positive treponemal antibody tests among the 22 in whom the tests were not performed was calculated according to the findings in the 24 in which the tests were performed. These calculations yielded only four chronic BFP reactors among the patients with rheumatoid arthritis or ankylosing spondylitis, less than 0.4 per thousand.

The present series included ten patients with a positive VDRL test suffering from diseases other than rheumatoid arthritis, ankylosing spondylitis, or SLE; in two of them, syphilis had been treated in the past, one having had clinical neurosyphilis and the other syphilitic aortitis. In six cases there was no available information about syphilis.

**Discussion**

The frequency of positive serological reactions for syphilis in a given series varies greatly with the composition of the series and also with the number and sensitivity of the serological tests employed. In the present series only the VDRL test was used as a screening procedure. At the present level of sensitivity this test detects about 90 per cent. of the chronic BFP reactions that can be detected with a battery of five tests (Wassermann, Cholesterol Wassermann, Kahn, Kolmer, VDRL: Lassus 1967). With these five tests the frequency of positive reactors among patients with definite SLE is 29 per cent. (Putkonen and others, 1967).

The incidence of false positive serological tests for syphilis in patients with rheumatoid arthritis has been estimated at 5 to 10 per cent. (Moore and Mohr, 1952; Kievitz and others, 1956). In the present series, the calculated frequency was only about 2 per thousand (22 cases), and in the majority of these cases the positivity was transient. The relative frequency of transient positive reactions may be related to intercurrent infections that are known to exacerbate the rheumatic disease and can thus lead to hospitalization of the patient.

The mean age of the patients with rheumatoid arthritis or ankylosing spondylitis, in the present series, was about 40 years, less than 10 per cent. being over 60 years of age. It has been reported that the frequency of positive serological tests for syphilis is markedly higher in the older age groups than in the general population (Tuffanelli, 1966). The same holds true for rheumatoid factors (Heimer, Levin, and Rudd, 1963). It may be difficult to differentiate between disease-association and age-association in a series including many old persons with rheumatic complaints. The present series, consisting of young and middle-aged patients, indicates that the incidence of the chronic BFP phenomenon in rheumatoid arthritis and ankylosing spondylitis is very low, hardly any higher than in the general population.

Of the 150 patients diagnosed as having systemic lupus erythematosus, only five had a positive VDRL test. The TPI test was performed in four of them, and two were TPI positive, one with no information about syphilis and the other with congenital syphilis treated as a child. One of the two TPI-negative patients had syphilis treated at the primary stage and the other denied having had syphilis. The patient in whom the TPI test was not done had a serologically-positive husband. This leaves only one definite false positive reactor in the group of 150 patients with SLE.
Summary
Serological tests for syphilis have been studied in patients treated in 1952-1966 at the Rheumatism Foundation Hospital, Heinola, Finland. All were screened with the VDRL test, which was positive in 97 cases (6.6 per thousand).

Of the positive cases, 82 had rheumatoid arthritis or ankylosing spondylitis. Clinical information and/or treponemal antibody tests, showed that sixty of these patients had syphilis. The great majority of the false positive reactions were transient, and the frequency of probable chronic BFP reactors was less than 0.4 per thousand.
