Lean, dry gout patients

L. GAIL DARLINGTON

From the Epsom District Hospital, Epsom, Surrey

Hypertriglyceridaemia is common in gout.1,2 Obesity may increase triglyceride concentrations, as may alcohol,3 but it remains uncertain whether obesity and alcohol, alone or in combination, are sufficient to explain the hyperlipidaemia in all cases. We looked for abnormal lipid concentrations in non-obese patients with gout who drank little or no alcohol to determine whether the hypertriglyceridaemia associated with gout occurred in such a lean and abstemious group.

All patients were of desirable weight or less for their age and frame4 and no patient drank more than one pint of beer per day or its equivalent. Such patients are rare, and only seven were found in four years from a busy clinic.

Fasting concentrations of lipid and lipoprotein were measured in serum at a laboratory with its own control population.5 Serum uric acid concentrations were determined for the patients with gout but unfortunately data for the control population were not available.

Readings for serum cholesterol, triglyceride, β-lipoprotein and prebeta lipoprotein concentrations in the patients with gout lay within 2 standard deviations of the corresponding mean for controls. This means that they were within the 95% confidence limits for the control population and it is therefore unlikely that there is any real difference between the patients with gout and control populations.

In spite of the small numbers of these ‘lean, dry’ patients, the results revealed no intrinsic hyperlipidaemia in subjects with gout when obesity and an excess of alcohol were removed as causes of hypertriglyceridaemia.

Cardiovascular disease and gout: a function of sex and age?

D. G. MACFARLANE

From the University Department of Medicine, Bristol Royal Infirmary, Bristol

Hypertriglyceridaemia is common in patients with gout and hyperuricaemia but it is still not known whether this results from a link between purine and lipoprotein metabolism or whether they occur together due to other associated facts, particularly obesity and high alcohol intake, both of which are commonly found in patients with hyperuricaemia.1 Nor is it firmly established whether patients with gout are, in fact, predisposed to premature cardiovascular disease, and, if so, whether the raised serum uric acid concentration operates as an independent risk factor, or only via its association with hypertriglyceridaemia and hypertension, which are established as cardiovascular risk factors in their own right.2 Another possibility—namely, that a raised serum uric acid concentration causes platelet hyperaggregatability and hence thrombosis—has recently been investigated in our unit with negative results.3
