Therapeutic effects on cartilage metabolism in arthritis as measured by release of proteoglycan structures into the synovial fluid

From the 1Department of Rheumatology, University Hospital, Lund; and the 2Department of Physiological Chemistry, University of Lund, Lund, Sweden

SUMMARY Proteoglycans are molecules that are degraded and released from the articular cartilage into the synovial fluid early in an arthritic process. Such released proteoglycans were quantified by an enzyme linked immunosorbent assay (ELISA). The proteoglycan content in synovial fluid from patients with various knee joint arthritides was constant in two samples withdrawn five days apart. To determine if therapeutic measures were paralleled by effects directly on the articular cartilage the patients were treated with local injections of glucocorticoids. In all patients the glucocorticoids induced a reduction of the proteoglycan content in the synovial fluid, reflecting their effects on the cartilage. In two patients with spontaneous remission of their arthritis a reduction in the proteoglycan content in the synovial fluid was also noted. The quantification of proteoglycans in synovial fluid appears to have potential as a useful tool for monitoring the effects of therapy on cartilage metabolism.

Key words: glucocorticoids, intra-articular injections, enzyme linked immunosorbent assay.

Proteoglycans are, after collagen, the major macromolecules of articular cartilage. They consist of a central protein core to which a large number of highly negatively charged glycosaminoglycan side chains, chondroitin sulphate and keratan sulphate, are covalently attached. The majority of the proteoglycans bind via the globular N-terminal region of their core protein to hyaluronic acid. Thus cartilage contains large aggregates of proteoglycans with molecular weights exceeding $10^5$, which are entrapped in the collagen network. A reduction of the proteoglycan content of the cartilage can be demonstrated early in inflammatory or degenerative joint disease. Histologically this can be observed as loss of metachromasia. It appears that the protein core is proteolytically cleaved and the fragments are free to diffuse out into the synovial fluid. The detection of proteoglycans in synovial fluid should accordingly be a marker for active cartilage destruction.

An ELISA detecting immunoreactive human articular cartilage proteoglycans in synovial fluid has been developed, in line with a previously described assay for dog articular cartilage proteoglycans released into synovial fluid. This method has potential as a useful tool for monitoring changes in proteoglycan content in synovial fluid longitudinally, e.g., in relation to different therapeutic approaches. The purpose of the present work was to use this assay to study the changes in proteoglycan content in inflammatory knee joint effusions after intra-articular glucocorticoid injections.

Materials and methods

Collection of synovial fluid

Eighteen patients (19 knee joints) were studied. One group (A) of nine patients (10 knee joints) all had an inflammatory knee joint effusion and had not received glucocorticoid treatment orally or intra-articularly for a minimum period of three months before the trial. None of these patients had been treated with slow acting antirheumatic drugs, and treatment with non-steroidal anti-inflammatory drugs.

Accepted for publication 31 October 1985.

drugs (NSAIDs) was not changed during the study.

The clinical characteristics of the patients in this
group are shown in Table 1. In most of the patients
in this group two initial measurements with a five
day interval were made before the glucocorticoid
was injected. Joint fluid was then sampled every five
days as long as synovial fluid could be withdrawn.
Group B represents samples from nine knee joints
collected for other purposes and analysed retrospec-
tively for this study. Two joint aspirations were
made in these patients and in all cases a relapse of
synovitis was present at the second aspiration de-
spite the glucocorticoid therapy. All patients in
group B had classical or definite rheumatoid
arthritis according to the American Rheumatism
Association criteria. Seven were Waaler-Rose
positive (titre ≥ 1/64). Four were treated with
chloroquine, one with Proresid (a podophyllin
derivative). All were treated with NSAIDs. No
glucocorticoids had been given orally or intra-
articularly during the three months before the first
joint aspiration. The knee joint radiographs in both
groups were graded by an independent radiologist
according to Larsen-Dale by comparing the radi-
ographs with standard pictures graded from 0 to 5,
where 5 denotes the most severe joint destruction.
The patients in both groups had moderate de-
struction (Table 1, group A). Joint aspirations were
made with a conventional aseptic technique by one
investigator for group A and by several investigators
for group B. No local anaesthesia was used. The
synovial fluid was withdrawn as completely as
possible by a 1-2 mm bore needle. The effusions were
collected in sterile EDTA tubes (ethylenedia-
inetetra-acetate, 5 mmol/l), centrifuged within one
hour (1800 g, 20 min, twice) to remove cells, and
then stored in aliquots at −80°C. Patients in group
A were given triaminolone hexaconidene (Leders-
pan), 10–20 mg and those in group B were given
betamethasone (Celestona bifas, 6–12 mg).

PREPARATION OF SYNOVIAL FLUIDS

Before analysis all synovial fluids were digested
with bovine testis hyaluronidase (Sigma, St Louis, USA)
to depolymerise the hyaluronic acid and to remove
the glycosaminoglycan side chains of the proteogly-
can. A predigestion to reduce the viscosity of the
synovial fluid was made by adding 2 µl of
hyaluronidase (1 mg/ml in 0-2 M trometamol
(TRIS), 0-1 M sodium acetate, pH 7-0) to 200 µl
of synovial fluid. After four hours at 37°C aliquots
(50 µl) were removed and mixed with 400 µl of 0-1 M
trometamol HCl (pH 8-0) containing 50 µl of
hyaluronidase. After four hours at 37°C samples
were frozen and kept at −20°C until analysis.

PREPARATION OF ANTIGEN

Proteoglycans were extracted from human articular
cartilage obtained at autopsy within a few hours
after death and purified by caesium chloride density
gradient centrifugation under the dissociative
conditions of 4 M guanidinium chloride. Proteo-
glycan preparations to be used for immunisation
were also purified by chromatography on Sephadex
G–200 eluted with 4 M guanidinium chloride.

PREPARATION OF ANTISERUM

Antibodies were raised in a goat immunised with
native human articular cartilage proteoglycan
monomer. Initially, 1-5 mg of proteoglycan
monomer in Freund’s complete adjuvant was
injected subcutaneously. Two injections a month
apart with 1-0 mg of proteoglycan monomer in
Freund’s incomplete adjuvant then sufficed to raise
antibodies in a titre sufficient for use in the immuno-
assay. The serum was used without further purifica-
tion. It did not react with any human plasma-
protein, showing that it was specific.

ENZYME LINKED IMMUNOSORBENT ASSAY

(ELISA)

An ELISA with specificity for human articular
cartilage proteoglycan monomer has been de-
veloped in accordance with a previously developed
method for dog articular cartilage proteoglycan.
Falcon polyvinyl microtitre plates (Falcon 3912)
were used. The wells were coated (24 hours, room
temperature) with 200 µl of human articular carti-
lage proteoglycan monomer (0-5 µg/ml). Before
coating the proteoglycans were treated with chon-
droitinase ABC (Seikagaku Kogyo Co Ltd, Tokyo,
Japan) to remove glycosaminoglycan side chains
for their use as antigen in the assay. Samples were
dissolved (1 mg/ml) in 0-1 M trometamol and 0-1 M
sodium acetate (pH 7-3) containing 0-01 unit/ml of
chondroitinase ABC, and digested for four hours
at 37°C. The solutions of chondroitinase treated
proteoglycans (1 mg/ml) were diluted in 0-05 M
sodium carbonate (pH 9-5) before coating the plates
overnight. The plates were extensively rinsed
with 0-15 M sodium chloride and 0-05% (w/v) Tween 20
to remove unbound proteoglycan. Samples of
synovial fluid (115 µl, pretreated with hyaluronidase)
were mixed with 115 µl of a 1/1000 dilution of goat
antihuman articular cartilage proteoglycan mono-
mer in 0-1 M sodium chloride, 0-05 M sodium
phosphate, and 0-05% Tween 20 (pH 7-5). After
preincubation for 24 hours at room temperature
200 µl of the mixture was added to the coated wells
of the microtitre plate. After incubation for 60
minutes at room temperature the plates were rinsed
as above and 200 µl of a dilution of rabbit antigoat

†A, B=measurements before glucocorticoid injection; C=measurement after glucocorticoid injection. Patients 9 and 10 were not given glucocorticoids.
IgG conjugated with alkaline phosphatase (Orion Diagnostica, Helsinki, Finland) in 0·1 M sodium chloride, 0·05 M sodium phosphate, 0·05% Tween 20, and 2 mg/ml of bovine serum albumin (pH 7·5) was added. After 60 minutes at room temperature the plates were again rinsed and 200 μl of enzyme substrate, 1 mg/ml of p-nitrophenyl phosphate in 1 M diethanolamine, pH 9·8, containing 0·5 mM MgCl$_2$, was added. The absorbance at 405 nm was measured in a Multiscan filter photometer (Flow laboratories, USA) immediately and after 60 minutes of incubation at room temperature. The increase in absorbance was used for calculations.

Results

In knee joints with clinically stable synovitis both the proteoglycan concentration and the total amount remained constant when aspirations were made twice with a five day interval before the glucocorticoid injection (Fig. 1). Apparently, removal of synovial fluid in itself did not affect the amount of proteoglycan fragments in the synovial fluid. After the glucocorticoid injection the proteoglycan content in the synovial fluid was much lower (Fig. 1). This finding was seen in all effusions except one (Fig. 1) which initially had a very low content of proteoglycans. Group B showed the same pattern, with stable proteoglycan concentrations in the two patients who received no injection and much lower concentrations in effusions after glucocorticoid injections (Fig. 2). Fig. 3 shows a marked decrease in proteoglycan content in knee joint No 1 after the glucocorticoid injection. The second injection 15 days later resulted in a slight further decrease. Four months after the first injection the proteoglycan content in the synovial fluid was still low despite a relapse of the synovitis, but five months later when a second relapse occurred the proteoglycan content in the synovial fluid had again risen to the initial amount. Two patients (knee joints Nos 9 and 10,

Discussion

Intra-articular injections of glucocorticoids effectively suppress joint inflammation.\textsuperscript{8} Their effects on the articular cartilage are less well established. Recently, however, several investigators have studied this problem by different approaches. Cocultures of cartilage and synovial tissue have shown that glucocorticoids can reduce cartilage degradation.\textsuperscript{9} The glucocorticoids seem to act on the synovial membrane by reducing the production of mediators causing cartilage degradation, i.e., catabolin and perhaps proteolytic enzymes.\textsuperscript{10} In a carrageenan induced synovitis, in studies of artificial synovial cavities in mice, hydrocortisone sodium succinate (a soluble preparation) reduced and hydrocortisone acetate (an insoluble preparation) enhanced proteoglycan loss from
implanted autologous cartilage as determined by a colorimetric procedure.11 When injected into the inflamed lining tissue both preparations reduced the proteoglycan loss. Another study with histological methods has shown reduction of cartilage degradation after triamcinolone hexacetonide injection into the knee joints of rabbits with an antigen induced arthritis.12 In healthy knee joints of rabbits, on the other hand, injection of hydrocortisone acetate has been shown to suppress the [3H]glycine incorporation in the cartilage, which according to the authors suggests a reduced synthesis of matrix components by the chondrocyte, in line with the known protein catabolic action of glucocorticoids in other tissues.13 In man only a few inconclusive radiographic studies have been performed. Chandler and Wright showed progressive reduction of the cartilage depth in knee joints after intra-articular injection of hydrocortisone despite clinical improvement.14 In the present study we use release of proteoglycans from the cartilage matrix as a marker for active processes. Previously, dogs with induced osteoarthritis of one knee joint were shown to have a higher concentration of proteoglycans in the diseased joint compared with that in the control joint.4 The most striking finding in the present study is the decrease in proteoglycan content in the synovial fluids after the glucocorticoid injections, suggesting a reduced liberation of proteoglycans from the cartilage. In a previous study of joint destruction the cartilaginous origin of the proteoglycans in the synovial fluid was indicated. When the cartilage mass became lower, as visualised by x ray, the proteoglycan content of the synovial fluid was markedly reduced.15 The quantification of proteoglycans in the synovial fluid presents some problems. Provided that the proteoglycans are liberated at a constant rate, the concentration of fragments will depend on the volume of the synovial fluid. This volume is difficult to measure. Isotope techniques have been tried16 but these are not suited for repeated measurements as in the present trial. In group A a standardised

Proteoglycan (PG) content (○) and joint leucocyte content (■) in knee joint synovial fluid samples from one patient (joint No 2) who did not benefit clinically from the glucocorticoid injection. The proteoglycan content decreased, while the joint leucocyte content remained constant.
Therapeutic effects on cartilage metabolism in arthritis

procedure was used to minimise sampling errors, most important when dealing with small effusions. The results from patient 6 (Fig. 1) show the importance of considering the synovial fluid volume in these studies. In this patient the changes in concentration and estimated total amount of proteoglycans differed considerably. In general, however, the trend is similar whether concentration or total amount is studied. Another potential problem when using immunoassay to quantify macromolecules could be that the fragments liberated react differently with the antibodies. In the present study, however, several of the samples analysed at different dilutions gave identical values, showing that the standards and the samples had reacted similarly with the antibodies.

The results presented show that glucocorticoids injected intra-articularly reduce the content of proteoglycan antigenic structures in the synovial fluid in inflammatory knee joint disease. When spontaneous remission of a synovitis occurs the content of proteoglycans is also reduced. Whether the effects of the glucocorticoid injections are caused by interference with the synthesis of proteoglycans or by inhibition of their degradation is not answered by the present study. It should be noted, however, that during tissue culture most newly synthesised matrix molecules are retained in the cartilage, favouring the latter mechanism.17 It is possible that the glucocorticoids inhibit production of catabolin in the inflamed synovium.10 The stimulus to the chondrocytes to catabolise proteoglycans would then decrease. The present investigation does not allow any conclusions about the long term effects of glucocorticoid injections, nor about the long term prognosis of the disease in a particular joint. It is possible that studies of the release of other cartilage matrix molecules may provide better prognostic tools.

Grants were obtained from Folksam's yrkesskadors stipstelse, the Swedish Medical Research Council (05 668), the Faculty of Medicine, University of Lund, Gretha och Johan Kocks stipstelser, Alfred Österlunds Stiftelse, Riksförbundet mot Reumatism, Föreningen för bistånd åt vanföra i skåne, and Lasaretts in Lund Fonder. We are grateful to Dr Holger Pettersson for examining the radiographs and to Sv Faltersson for skilful technical assistance.
