Binding of sodium aurothiomalate to human serum albumin in vitro at physiological conditions

SUSANNE MØLLER PEDERSEN

From the Department of Clinical Chemistry, Odense University Hospital, Odense; and the Rheumatism Unit, Aarhus University, Aarhus, Denmark

SUMMARY The binding of aurothiomalate to human serum albumin was studied by equilibrium dialysis at 37°C, pH 7.3-7.4, and ionic strength 0.15-0.16 mol/l. It was found that aurothiomalate was bound to albumin at one site with an apparent association constant $K_1=3.0\times10^4$ M$^{-1}$ and at three or more sites with the sum of association constants of the order of $10^3$ M$^{-1}$. Valuable information of the aurothiomalate-albumin interaction was deduced from the observed changes of pH of the albumin solutions during dialysis. A conceivable binding mechanism consistent with the results might be that aurothiomalate binds as Au$^+$ to the high affinity binding site by exchanging a H$^+$ and that this site might be the sulphhydryl group in cysteine$^{34}$; and that aurothiomalate binds as monomeric anions to the lower affinity binding sites.

Key words: gold, Myocrisin, Sanocrysin, aurothiosulphate, protein binding, equilibrium dialysis, binding mechanism, gold therapy.

Gold salts in the form of thio complexes have been used successfully in the treatment of rheumatoid arthritis for more than 50 years. Important aspects of their pharmacokinetics and mode of action, however, are still unknown. Several reports indicate a lack of correlation between the total concentration of gold in plasma and therapeutic and toxic effects.$^{1-8}$ In vivo and in vitro experiments suggest that most of the gold in the circulation is bound to albumin.$^{2-8,10}$ Since it is conceivable that the clinical effects might be correlated with the non-protein bound gold concentration this value might be a more useful parameter for monitoring patients during chrysotherapy. In order to calculate the free gold concentration in plasma (or serum) reliable values for the apparent association constants are needed.

Very little quantitative information concerning the binding of gold compounds to human serum albumin is available. Danpure found that aurothiomalate was bound to human albumin in vitro at a single site, of which 0.7 sites had an apparent association constant of $1.5\times10^5$ M$^{-1}$ and 0.3 sites had an apparent association constant of $1.1\times10^5$ M$^{-1}$. Mason found that aurothiomalate was bound to albumin in vitro at a single site with an association constant $K_1=6.0\times10^3$ M$^{-1}$ and at 6-6 sites with $K_2=2.35\times10^2$ M$^{-1}$. Pedersen found that aurothiosulphate was bound to human albumin in vitro at one site with an association constant $K_1=3.0\times10^4$ M$^{-1}$ and at three or more sites with the sum of the association constants equal to $1.6\times10^3$ M$^{-1}$. These results differ considerably from each other possibly owing to the different techniques employed or to the different analysis of the binding data, or for both these reasons.

Reliable association constants are of clinical importance as gold compounds on empirical base are administered in equivalent doses with respect to gold content. In the study presented here the binding of sodium aurothiomalate to human serum albumin was investigated in vitro at physiological conditions with respect to albumin concentration, pH, temperature, and ionic strength. As it was found that aurothiomalate was strongly bound to the dialysis membrane an equilibrium dialysis system was used, with the great advantage that partial adsorption to the membrane does not influence the results.$^{13}$ The experimental conditions and the analysis of the binding data are identical to those previously described for the binding of aurothiosulphate to human albumin.$^{12}$ It is, therefore, possible to compare the results obtained for the two gold compounds.
Materials and methods

Materials
The albumin preparation used was purified, lyophilised human albumin (Behringwerke AG, Marburg, West Germany). The albumin preparation fulfilled the criteria for purity specified by Hobbs et al. Polyacrylamide gradient gel (PAA 4/30, Pharmacia, Uppsala, Sweden) electrophoresis of a 0.5% albumin solution showed only one distinct band of monomer albumin and one very faint band due to dimers. Crossed immunoalectrophoresis performed against rabbit antiserum (Dako, Copenhagen, Denmark) showed that no proteins other than albumin were detectable. The sodium aurothiomalate (AuSH₂C₄O₄Na₂) was purchased from Rhône-Poulenc Pharma Norden, Birkerød, Denmark. The visking seamless cellophane tubing (8/32 inch, Union Carbide Corporation, Chicago) used for dialysis was washed and prepared as described by Pedersen. All initial solutions of albumin, aurothiomalate, and blanks were unbuffered solutions prepared in distilled, sterile water containing 0.15 M NaCl and with pH adjusted to 7.50 in order to obtain pH = 7.4 at equilibrium (see below).

Equilibrium dialysis
The binding of aurothiomalate to human albumin in unbuffered solutions at 37°C, pH 7.3-7.4, and ionic strength 0.15-0.16 M/l was studied in an equilibrium dialysis system containing initially 1 ml albumin solution on the inside and 3 ml aurothiomalate solution on the outside of the membrane with a range of concentrations of total sodium aurothiomalate from 102 μmol/l to 2051 μmol/l.

Control tubes, with aurothiomalate solution on the outside and blanks on the inside of the dialysis membrane, were set up at two different aurothiomalate concentrations in duplicate to establish that equilibrium was reached at the end of the experiment. During dialysis the samples were vertically rotated in order to obtain equilibrium within 48 hours. After equilibrium was reached the concentration of albumin was measured inside and the pH and concentrations of gold and sodium were measured on both sides of the dialysis membrane.

Ionic strength
According to general practice the contribution of albumin to ionic strength was ignored and it was found that, in the concentration range of sodium aurothiomalate used, the contribution of aurothiomalate to the ionic strength in each albumin solution could be neglected.

pH
During dialysis it was found that pH decreased by 0.15-0.30 pH units in the albumin containing solutions and by approximately 0.20 pH units in the solutions free of macro-ions. The changes in pH during dialysis are illustrated in Table 1. In order to obtain pH equal to 7.3-7.4 at equilibrium the pH was adjusted before dialysis to 7.50-7.55 in each initial solution.

Measurements
For albumin determinations a quantitative electroimmunoassay technique was used according to the principles of Laurell (albumin standard: standard human serum, Behringwerke AG). The gold concentrations were determined with a flameless atomic absorption spectrophotometer (Beckman model 485 fitted with a Masmann cuvette model 1268) as described by Pedersen and Graabaek. All pH measurements were performed at 37°C with a Radiometer pH meter PHM 72 supplied with the electrode system BMS 2 MK 2 blood microsystem.

Results
Fig. 1 shows the experimental data for the binding of sodium aurothiomalate to human serum albumin at neutral pH; the temperature was 37°C and the ionic strength 0.15-0.16 M/l in all solutions. The binding data are plotted as ν versus log C, where ν is the average number of gold atoms bound (in one form or another) per albumin molecule and C is the equilibrium concentration of unbound gold. In the present study the total concentration of gold was determined on both sides of the dialysis membrane when equilibrium was reached. The measurement on the inside yields the sum of protein bound and

non-protein bound gold. That of the outside is a measure of non-protein bound gold. The protein bound gold was then calculated as the difference between total gold and non-protein bound gold; and \( v \) evaluated by the equation \( v = \frac{[\text{albumin bound gold}]}{[\text{albumin}]} \). The molecular weight of albumin was assumed to be 67,000 throughout.

Although the gold or gold complex are probably present as ions, no correction for the Donnan effect was made as the concentration of added salt (0.15 M NaCl) was sufficiently high to suppress this; e.g., the observed distribution factor for Na⁺ across the semipermeable membrane \((\text{Na})/(\text{Na'})\) was 1.01, where the primed symbol indicates the side of the membrane free from macro-ions.

The lines in Fig. 1 are the best fit to the equation:

\[
\bar{v} = \sum_{i=1}^{n} \frac{K_i \cdot C}{1 + K_i \cdot C} \tag{1}
\]

using a non-linear least square curve fitting procedure. The summation is over all \( n \) sites of the albumin molecule, and \( K_i \) is the association constant for site \( i \). Equation (1) implies that there is no interaction between the sites. The maximum number of binding sites, \( n \), is not known and was, therefore, varied in the calculations. The binding

data (ν, C) for small gold concentrations (indicated by (●) in the figure) could not be fitted to the calculated lines and were therefore not included in the analysis. The reason for this interesting discrepancy at small gold concentrations is under further investigation. If these binding data were included, however, the association constant K, was increased by 60% and the other constants remained virtually unchanged.

Table 2 summarises the binding results obtained for the three independent sets of experimental data considered separately or as a single set. The results show that there is a single high affinity binding site with an association constant K1=3×10⁴ M⁻¹ and three or more lower affinity binding sites with association constants of the order of 10³ M⁻¹. The best fit to equation (1) was significantly improved by increasing n from three to four, but only minor changes of the rms values resulted when n was increased beyond four. The possibility that more than four binding sites exist cannot be excluded. The association constants for sites two to four were identical. The results did not depend on whether the three sets of experimental data were analysed separately or as a single data set.

Discussion

In the present investigation it was found that aurothiomalate was bound to human serum albumin in vitro at one site with an association constant K1=3×10⁴ M⁻¹ and at three or more sites with the sum of association constants of the order of 10³ M⁻¹.

In an attempt to identify the combining sites and understand the mode of action of the compound the values of the association constants and the number of combining sites might be important. For clinical purposes, however, it is the determination of the equilibrium constant k₁, equal to the sum of the calculated association constants (∑ν Kν), which is of interest. The range of k₁ values is 2·7×10⁴ M⁻¹ to 3·6×10⁴ M⁻¹, with n=3 to n=8. These values of k₁ correspond to 94–96% binding of gold to human serum albumin under physiological conditions.

Mason’s results for the binding of aurothiomalate to human albumin give a value of k₁ which corresponds to 80–82% binding of gold to human serum albumin. The lower degree of binding of aurothiomalate might be due to problems of drug-membrane binding in the ultrafiltration method used in this study. The association constants obtained by Danpure may not be reliable owing to an inadequate analysis of the binding data.

The degree of gold binding found in this study agrees well with the results obtained by Mas-
binding of monomer aurothiomalate anions, AuSH₃C₆O₂⁻, to the lower affinity binding sites.

There is evidence that aurothiomalate exists as a polymer in aqueous solutions, 23-25 though its precise chemical nature has not yet been established. 26 The degree of polymeric association is known to be strongly dependent on ionic strength, aurothiomalate concentration, and pH of the solution and decreases with decreasing concentration and ionic strength. 25 In the present experiments both the ionic strength and the aurothiomalate concentrations are much smaller than those used in the structural investigations mentioned above and, therefore, the possibility that monomer aurothiomalate is the main constituent in the investigated solutions cannot be excluded. The possible presence of polymeric forms in the solution is interesting and noteworthy and is also consistent with the above analysis if these polymers are broken down to monomers upon binding.

The suggested binding mechanism supports the finding of free thiomalate in plasma and urine of patients receiving sodium aurothiomalate. 27-29 Due to these findings and the structural resemblance of penicillamine and aurothiomalate ligands it has been suggested that thiomalate might be the active metabolite in 'gold' therapy. 27-29 From the essentially identical binding results obtained for the binding of sodium aurothiosulphate to human serum albumin 12 one could equally suggest that thiosulphate might be the active metabolite in aurothiosulphate therapy, as no differences in clinical effects of the two compounds have ever been reported. The two compounds have no structural resemblance except that both are drugs containing thiol. If the above mentioned suggestions are correct this opens some very interesting perspectives for future treatment of rheumatoid arthritis; and for the same reasons as mentioned for thiomalate 29 a controlled trial of thiosulphate is clearly indicated.

Although attention is now being paid to the possible antirheumatic activity of the thiomalate and thiosulphate ligands, it should not be forgotten that gold compounds have been popular drugs for the treatment of many diseases for centuries. Thiosls were first introduced as Au(I) stabilising ligands between 1913 and 1927, a period of intense searching for Au(I) compounds of lower toxicity. It is still likely that it is the free concentration of the gold thio complexes in the tissue fluids which determines pharmacological activity. As these compounds are strongly bound to human serum albumin, minor changes in the binding affinity or capacity might give rise to a major change in the free 'gold' concentration, which could induce unwanted clinical effects. The lack of correlation between total gold concentration in plasma and clinical effects is easily understood. There might, however, be a correlation between the free gold concentration in plasma and therapeutic and toxic effects. This remains to be evaluated. For practical clinical purposes it is not possible to determine the in vivo free 'gold' concentration. Knowing the association constants, the albumin concentration, and the total concentration of 'gold' in plasma or serum, it is possible to calculate the free 'gold' concentration. The present results show that under physiological conditions no significant difference in the binding of aurothiomalate and aurothiosulphate to human serum albumin could be demonstrated.

The author is greatly indebted to Mrs Inge Biblet for skilful technical assistance.
