SUMMARY We evaluated the effect of dipyridamole on thallium-201 myocardial perfusion in 23 patients with progressive systemic sclerosis (PSS) with diffuse scleroderma. Thallium-201 single-photon emission computed tomography (SPECT) was performed at rest and after coronary artery vasodilatation with intravenous dipyridamole (0.14 mg/kg/min for four minutes). The left ventricle was divided into nine segments; each segment was graded as 2-0, 1-5, 1-0, 0-5, 0-0 (zero represents no activity). Dipyridamole significantly improved resting thallium-201 myocardial perfusion: the mean (SD) number of segments with thallium defects decreased from 6.0 (2.1) at rest to 4.1 (2.5) after dipyridamole (p<0.0001); the mean (SD) score in segments with resting defects increased from 0.92 (0.24) at rest to 1.13 (0.38) after dipyridamole (p<0.0001); the mean (SD) global score per patient increased from 10.2 (1.8) at rest to 11.4 (2.1) after dipyridamole (p=0.02); the global score increased by at least 2-0 in 12 patients and worsened by at least 2-0 in three patients only (p=0.05). The results of this acute study suggest that some drugs with potent vasodilator activity on small coronary arteries may be beneficial in the treatment of PSS patients with thallium-201 myocardial perfusion abnormalities.

Primary scleroderma myocardial disease (PSMD) is an important complication of progressive systemic sclerosis (PSS) and accounts for a significant proportion of the mortality in this disease.1-4 The pathogenesis of primary scleroderma myocardial disease remains uncertain.1-3 The cause of the myocardial necrosis and fibrosis that occurs in the setting of normal extramural coronary arteries is not fully understood, and the possibility that these lesions are a reflection of a primary fibrous tissue overgrowth leading to secondary vascular compromise is still reasonable.1-3 5-7 Nevertheless, a growing body of evidence from studies of the heart and other organs involved in progressive systemic sclerosis suggests that the vascular system per se may be the primary target organ in PSS and that the myocardial lesion is a manifestation of focal ischaemic injury resulting from functional vascular disease, with or without accompanying structural change.1-3 8-14

Bulkley reported a high prevalence of myocardial contraction band necrosis—a histological lesion seen in the setting of ischaemic injury followed by reperfusion—and speculated that myocardial fibrosis results from intermittent spasm of the small coronary arteries, a form of 'myocardial Raynaud's phenomenon'.2 Additional support for this hypothesis has been provided by other investigators, who demonstrated cold induced abnormalities on thallium perfusion in patients with PSS.12-13 Follansbee et al showed that the majority of patients with PSS and diffuse scleroderma had thallium-201 myocardial perfusion defects.13

Since abnormalities of small coronary arteries may have an important role in primary scleroderma...
myocardial disease, vasodilator drugs could be beneficial in PSS patients with myocardial involvement. In the present study we evaluated the effect of the coronary vasodilator dipyridamole on thallium-201 myocardial perfusion in patients with diffuse scleroderma, using single photon emission computed tomography (SPECT).

Patients and methods

Patients with progressive systemic sclerosis
Twenty-three patients with PSS with diffuse scleroderma were studied. All patients satisfied the American Rheumatism Association preliminary criteria for definite systemic sclerosis. In addition to skin thickening of the fingers, hands, and forearms, all patients also had truncal involvement (diffuse scleroderma). None of the patients had the CREST syndrome variant (calcinosis, Raynaud’s phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia) of PSS.16 Twenty-one of the 23 patients were women. The mean age (SD) was 51.5 (8.5) years (range 35–66). The duration of disease ranged from one to 30 years (mean SD 11.8 (9.3) years). Patients were excluded if they had severe pulmonary or renal involvement. Twenty-two patients had Raynaud’s phenomenon, 10 of whom also had a history of digital ulcers. At the time of the study none of the patients was taking medication for cardiac or vascular disease. All patients gave informed consent for all procedures.

Non-invasive examination procedures
All patients with PSS had the following performed: physical examination, pulmonary function testing (routine spirometry with forced vital capacity (FVC), forced volume in one second, and single-breath diffusing capacity for carbon monoxide (DLco)), electrocardiograms, standard anteroposterior and lateral chest roentgenograms, and two dimensional echocardiograms.

Resting and dipyridamole thallium-201 imaging
All PSS patients underwent thallium-201 myocardial single photon emission computed tomography, at rest and after coronary artery vasodilatation with intravenous dipyridamole.21–25 Resting and dipyridamole studies were performed at one week intervals. The one week delay between the two investigations was preferred to the four hour redistribution images, mainly because of the lack of information about the elimination rate of dipyridamole by the myocardium of PSS patients. The order of performing resting and dipyridamole studies was alternated.

Thallium-201 imaging was performed with the subject at rest, using a tomographic gammacamera (CGR Gammatome T 9000). The patient was placed supine with the left arm stretched over the head. Thallium-201 (Mallinckrodt Diagnostica) with an activity of 75 MBq (2.0 mCi) was injected intravenously. Acquisition began within 15 minutes of the tracer administration. Thallium images were recorded for 20 minutes. Thirty two images were recorded on a 180° rotation basis, each of them digitised in a 64 × 64 matrix. Approximately two million counts were accumulated in one study. About 20 transverse slices (6 mm thick) were reconstructed on a minicomputer (CGR IMAC).

Dipyridamole-thallium imaging was performed with the patient in the supine position. Intravenous dipyridamole (Boehringer-Ingelheim) was infused through a 21 gauge butterfly needle placed in a forearm vein. A calibrated infusion pump delivered the drug at 0.14 mg/kg of body weight/min for four minutes. Blood pressure, heart rate, and electrocardiograms were monitored and all symptoms recorded. One minute after the end of dipyridamole infusion 75 MBq (2.0 mCi) activity of thallium-201 was injected intravenously and the cannula was flushed with 5 ml of saline. The imaging procedure was begun within five minutes of the time of thallium injection. Aminophylline (250 mg), which promptly reverses the effects of dipyridamole, was available during each procedure.

Analysis of thallium-201 images
The thallium-201 images were interpreted from a computer display. The resting and unprocessed dipyridamole images were displayed side by side for comparison. The use of the same amount of injected radioactivity reduced the normalisation bias observed between different tomographic studies. Each image was interpreted by three independent experienced observers without knowledge of the patient’s clinical history and catheterisation findings. The readers were blinded to pre- and post-dipyridamole scans. Such a qualitative interpretation of thallium images by multiple observers is a highly sensitive and specific test for coronary artery disease.22

The analysis was done by visual inspection of the left anterior oblique sets of images, using the three most central slices of the left ventricle (apical, central, and basal). Each of these three slices was divided into three segments (Fig. 1). Thus the left myocardium was divided into nine segments. Tracer activity in each segment was visually graded as 2-0,
Fig. 1  Schematic representation of the thallium-201 myocardial emission tomography. The three most central slices are shown (left anterior oblique view). Each of the three slices was divided into three segments (1 to 9). LAO = left anterior oblique.

1-5, 1-0, 0-5, 0, as previously described. A value of 2-0 represents the most intense thallium-201 activity and zero represents no activity. The range of normal for each segment was determined from studies of 20 normal control subjects (18 women, two men, mean age (SD) 53-6 (8-1) years, range 35–64 years) evaluated in our laboratory. The three observers' scores for each segment were averaged. Segmental defects on thallium-201 myocardial scans were defined as mean scores of less than 1-5, as previously reported.

If the mean segmental score after dipyridamole increased or decreased by at least 0-5 compared with resting values it was interpreted as an improved, or aggravated, defect.

If the mean segmental score after dipyridamole increased by at least 0-5 and was 1-5 or greater it was interpreted as 'improved', or 'aggravated' in each patient a 'global score' was calculated by summing the mean scores of each segment (maximal global score = 18, minimal global score = 0). If the global score after dipyridamole increased or decreased by at least 2-0 compared with resting values it was interpreted as 'complete improvement'.

In the patients underwent supine resting radionuclide ventriculography with a gammacamera (CGR Acticamera), using in vitro labelling of red blood cells with 555 MBq (15 mCi) of $^{99m}$Tc. Resting gated blood pool images were acquired for 300 000 counts in each of the 16 frames. The best left anterior oblique view with a 10° caudal tilt was used to separate the ventricles from the atrial images. Left ventricular ejection fraction was determined by an automatic thresholding technique for background subtraction. Normal resting left ventricular function was defined as an ejection fraction of $\geq 55\%$.

Regional wall motion was qualitatively graded as normal or hypokinetic. The regional wall motion abnormalities were classified in three segments matched as closely as possible to the segmental distribution used to grade the thallium-201 images. Differences of opinion between the three independent observers were resolved by consensus.

CATHETERISATION PROCEDURE
Nine patients underwent cardiac catheterisation with left ventricular angiography and coronary arteriography according to standard techniques. The coronary angiograms were interpreted independently by two experienced observers without knowledge of the scan findings. No patient had an interval change in cardiac symptoms or electrocardiograms during the study period.

STATISTICAL METHODS
Statistical analyses were made with Student's paired and unpaired $t$ test, the sign test, and the correlation test. Calculations were carried out according to the biomedical data program. Significance was considered present if $p \leq 0.05$.

Results

CLINICAL FINDINGS
None of the PSS patients had either a previous history of systemic hypertension or a blood pressure above 140/90 mmHg during the evaluation. None of the patients had evidence of congestive heart failure. Nine patients had chest pain consistent with angina pectoris. Five patients had abnormal findings on electrocardiograms, including one with a pseudoinfarction pattern, three with ST segment depression, and one with left bundle branch block. Nine of the patients had cardiac enlargement on standard chest roentgenograms. Echocardiograms showed minimal posterior pericardial disease in four patients.

Chest radiographs showed normal findings in 15 patients and mildly abnormal interstitial markings in eight. Pulmonary function findings were normal in 11 patients. Twelve patients had mild restrictive lung disease (FVC 66–80% of predicted normal) or an isolated decrease in $\text{DLCO}$ (66–80% of predicted normal). None of the patients had either physical findings of severe pulmonary hypertension or electrocardiographic evidence of right ventricular hypertrophy.
Effect of dipyridamole on thallium-201 myocardial perfusion in PSS

DD = disease duration; LVF = left ventricular function; REF = resting left ventricular ejection fraction; WH = wall hypokinesia; R = rest; DPD = after dipyridamole; After DPD Imp = improved segments after dipyridamole; After DPD Unc = unchanged segments after dipyridamole; After DPD Agg = aggravated segments after dipyridamole; GS = global score.

All 23 patients had normal serum creatinine concentration (mean (SD) 74 (14) µmol/l).

Resting Radionuclide Ventriculography

Resting left ventricular ejection fraction, assessed by radionuclide ventriculography, was normal in all but three PSS patients (mean (SD) 62(8)%), range 49–77% (Table 1).

Ten patients had hypokinetic regional left ventricular wall motion at rest. All regional wall motion abnormalities were associated with resting thallium defects in the same territories.

Resting and Dipyridamole Thallium-201 Imaging

The results are shown in Table 1.

All 23 PSS patients had abnormalities on resting thallium scans. Since the left myocardium was divided into nine segments in each of the 23 patients, a total of 207 segments was studied. Resting thallium defects were found in 138 segments (67%). The mean (SD) number of resting thallium defects in each patient was 6.0 (2.1) (range 2–9; with a median defect number of 6.0 for all 23 patients).

After dipyridamole infusion 55 thallium defects (40%) were improved (increase in mean score of ≥0.5), 64 defects (46%) remained unchanged (variation in mean score of <0.5), and 19 defects

Fig. 2 Resting and dipyridamole-thallium scans showing improvement in a representative patient. There are two defects on the resting images (upper left and upper right: arrows) that fill in on the dipyridamole images (lower left and lower right). LAO 45° left anterior oblique.
(14%) worsened (decrease in mean score of ≥0.5). Improvement induced by dipyridamole in a representative patient is shown in Fig. 2.

In each patient an ‘improvement index’ was calculated as the ratio:

\[
\frac{\text{number of improved segments} - \text{number of worsened segments}}{\text{number of segments with resting thallium defects}}
\]

The mean (SD) ‘improvement index’ (0.27 (0.47)) was significantly different from 0 (p<0.02, by the t test).

After dipyridamole infusion 43 of the 55 improved segments had a score of ≥1.5 and were considered to be normal. Thus the mean (SD) number of segments with thallium defects significantly decreased from 6.0 (2.1) at rest to 4.1 (2.5) after dipyridamole (p<0.0001 by the paired t test).

In the 138 segments with resting thallium defects the mean (SD) score significantly increased from 0.92 (0.24) at rest to 1.13 (0.38) after dipyridamole (p<0.0001 by the paired t test).

The mean (SD) global score significantly increased from 10.2 (1.8) at rest to 11.4 (2.1) after dipyridamole (p<0.02, by the paired t test).

After dipyridamole the global score improved by at least 2.0 in 12 patients and worsened by at least 2.0 in three patients only (p=0.05, by the sign test).

Thus dipyridamole significantly improved all parameters of myocardial perfusion in patients with PSS and diffuse scleroderma.

The thallium results did not correlate with the age of the patients, or with the disease duration, or the resting left ventricular ejection fraction. The differences in thallium results were not statistically significant between patients with chest pain, or interstitial markings, or abnormal pulmonary function findings, and the remainder. Patients with electrocardiogram (ECG) abnormalities, however, had significantly greater numbers of resting thallium defects than did the remainder (mean (SD) 8.0 (0.7) v 5.4 (2.1), p<0.0003). Patients with hypokinetic regional wall motion had significantly greater numbers of resting thallium defects and lower resting global scores than did the remainder (mean (SD) 7.2 (2.0) v 5.1 (1.8), p<0.02; and 9.1 (1.7) v 8.0 (1.5), p<0.01 respectively). Finally, the improvement in global score inversely correlated with the resting global score (r=0.48; p<0.02); the best improvement was noted in patients with the lowest resting global scores.

**ADVERSE EFFECTS OF DIPYRIDAMOLE**

Dipyridamole was well tolerated by most of the patients in the study. In most patients systolic blood pressure decreased by 5–10 mmHg (mean (SD) 5 (5) mmHg) and heart rate increased by 5–15 beats per minute (mean (SD) 11 (8)) during the infusion. Three patients complained of mild symptoms, such as transient dizziness, headache, or nausea. None of the patients developed chest pain or any modifications of electrocardiograms after dipyridamole infusion. The adverse effects did not require any treatment or alteration in the protocol. None of the patients was given intravenous aminophylline.

**CATHETERISATION RESULTS**

Eight of the nine patients who underwent cardiac catheterisation had normal left ventricular function. In one patient the left ventricular end diastolic volume and left ventricular mass were increased to 109 ml/m² and 107 g/m² respectively, and ejection fraction decreased to 46%. The coronary arteriograms results were normal in all but one patient, who had 80% stenosis of a small lateral artery. This stenosis did not correlate with a thallium perfusion defect (at rest or after dipyridamole) or with a wall motion abnormality. Two of the three patients with dipyridamole induced aggravation in thallium defects underwent cardiac catheterisation and had normal coronary angiography.

**Discussion**

The major observation in this study was that dipyridamole significantly improved thallium-201 myocardial perfusion in patients with progressive systemic sclerosis with diffuse scleroderma. After dipyridamole infusion the mean number of segments with thallium defects significantly decreased, the mean score of segments with resting thallium defects, and the mean global score significantly increased.

These findings are consistent with clinical and histopathological results, suggesting an abnormality of the small coronary arteries in primary scleroderma and myocardial disease. Symptoms of PSMD include chest pain, dyspnoea, palpitations, congestive heart failure, syncope, and sudden death. Angina pectoris and myocardial infarctions have been seen in PSS patients with normal coronary arteries. Concentric intimal hypertrophy, narrowing, fibrosis, and fibrinoid necrosis of intramural coronary arteries and arterioles have been noted in some studies but not in others. Bulkley reported pathological findings consistent with progression from contraction band necrosis through replacement...
fibrosis in hearts of PSS patients. The recent studies by Follansbee et al.13 and Kahan et al.14 also suggested that in association with myocardial fibrosis a functional or structural abnormality of the coronary circulation might be present at the level of the intramyocardial vasculature. In the latter study14 the normal mean coronary sinus blood flow at rest in PSS patients with numerous resting thallium defects might be explained by a heterogeneous myocardial perfusion. In this context it is relevant that patients with significant atherosclerotic coronary stenoses may have a normal coronary sinus blood flow at rest, despite frequent thallium-201 perfusion defects.25 In PSS patients the dipyridamole induced increase in coronary sinus blood flow14 could be due to vasodilation in normal zones, or in territories with vasospasm of the small coronary arteries, or to collateral vessels that function only after coronary artery vasodilatation. The limitation in coronary reserve14 could be due to fibrotic zones or to anatomical lesions of the small coronary arteries. Follansbee et al demonstrated a high prevalence of abnormalities of myocardial perfusion that can be detected by means of radionuclide techniques in patients with PSS.13 These investigators used exercise and redistribution thallium-201 planar scintigraphy. The present study is the first to use thallium-201 myocardial single photon emission computed tomography to assess the effect of dipyridamole on myocardial perfusion in systemic sclerosis. Emission tomography provides a better sensitivity and also a better interobserver agreement than planar scintigraphy in the detection of transmural myocardial necrosis with thallium-201.19 20 Furthermore, since histological lesions are small and patchy in primary scleroderma myocardial disease, emission tomography appears to be a more sensitive method than planar scintigraphy (which does not resolve depth) in these patients. Indeed, we found a very high prevalence of resting thallium defects in PSS patients.

Patients with abnormalities on ECG had significantly greater numbers of resting thallium defects than did the remainder. These findings are consistent with those of a recent study which showed that thallium defect scores were greater in PSS patients with septal infarction pattern or ventricular conduction abnormalities than in the remainder.29 Patients with hypokinetic regional wall motion had significantly greater numbers of resting thallium defects and lower resting global scores than did the remainder. These results are consistent with the hypothesis that myocardial dysfunction in these patients may be related to both fibrotic and vascular abnormalities.

The coronary flow response to dipyridamole is at least as great as that associated with exercise, but without the physiological increase in myocardial oxygen demand.21 30-32 Most studies indicate that treadmill exercise is usually associated with a threefold increase in coronary blood flow.30 Dipyridamole increases coronary blood flow three to fivefold.31 33 The increase in coronary blood flow that occurs with exertion quickly disappears after cessation of exercise; the coronary dilatation secondary to dipyridamole infusion declines at a rate of 50% per 45 minutes in normal subjects.33 The side effects of intravenous dipyridamole are probably not greater than those associated with treadmill exercise tolerance tests in patients with coronary artery disease.21 32 Indeed, in the present investigation no PSS patient developed serious side effects: thus dipyridamole appears to be safe in patients with primary scleroderma myocardial disease. Finally, dipyridamole can increase coronary blood flow in patients who cannot achieve intense levels of exercise, such as PSS patients.

Several investigators have shown that in conjunction with a dipyridamole infusion, thallium-201 scans reliably detect coronary artery disease.21 22 24-26 In these patients with structural lesions of the large coronary arteries and reversible ischaemia, hypoperfused segments after dipyridamole have a normal or improved perfusion at rest; non-perfused necrotic segments show no change between dipyridamole and rest. In a few cases a 'reverse' redistribution phenomenon has been described: segments that appear normal after dipyridamole are hypoperfused at rest; this may be explained by the existence of collateral vessels that function only under conditions of stress.27

The present findings are in marked contrast with those usually obtained in patients with coronary artery disease. We showed that dipyridamole significantly improved thallium-201 myocardial perfusion abnormalities in PSS patients. It should be noted that patients with the best dipyridamole induced improvement had the lowest resting global scores. These findings may be explained by a high prevalence of reversible (vascular) abnormalities, suggesting that vasodilator drugs may be beneficial even in PSS patients with severe thallium-201 perfusion abnormalities at rest. The mechanism of action of dipyridamole on thallium-201 myocardial perfusion defects in our patients cannot be determined from this study. These results, however, are compatible with the hypothesis that the previously discussed abnormalities may coexist in variable proportions in different myocardial segments and patients. A resting thallium defect due to vasospasm of the small
coronary arteries may be improved after coronary artery dilatation with dipyridamole. The hypothesis that the dipyridamole induced increased perfusion of normal areas surrounding some defects might make defects appear to diminish, while in fact the perfusion of the fibrotic areas may not be changed, cannot be excluded; however, this possibility is considerably reduced by the tomographic technique, as compared with planar scintigraphy. Conversely, resting thallium defects due to fibrosis or to anatomical lesions of the intramyocardial vasculature may be unchanged or even aggravated after dipyridamole, as previously described in patients with severe atherosclerotic stenoses of the large coronary arteries. 34 35

The results of the present study demonstrate that dipyridamole significantly improves thallium-201 myocardial perfusion in patients with progressive systemic sclerosis with diffuse scleroderma. A long term controlled study of small coronary artery vasodilator drugs in the treatment of PSS patients with myocardial perfusion abnormalities is warranted.

We thank Mrs Magali Vallet-Amor for expert secretarial assistance.
