From the 1Department of Clinical Sciences, University of Tampere, Tampere, Finland; 2Tampere Research Station of Sports Medicine, Tampere, Finland; and 3Orivesi Health Centre, Orivesi, Finland

SUMMARY All visits to physicians in the Orivesi Region Federation of Municipalities for Public Health Work in Finland paid due to symptomatic osteoarthrosis of the knee joint were prospectively recorded over a period of one year. Two hundred and thirty four visits were made, accounting for 0.63% of all visits. The prevalence of knee osteoarthrosis was 1.11% (men 0.45%, women 1.72%), and the incidence was 0.60%. The disease occurred almost twice as often in the right knee than in the left. The study provides basic information about patients needing medical help because of symptomatic knee osteoarthrosis. The results can be used as an aid to the planning of examination and treatment resources and in assessment of the need for such services.

Rheumatic diseases are one of the most common public health problems and they have become increasingly prevalent in Finland1 and other industrialised countries.2-5 The prevalence of osteoarthrosis, especially, has increased in recent years.6,7,8 According to Klaucka et al the prevalence of osteoarthrosis in Finland increased markedly in 12 years; whereas the prevalence in 1964 was 0.7% by 1976 it had risen to 3.2%. During the same period the prevalence of rheumatoid arthritis remained constant (1.1% and 1.2%).

Epidemiological studies have not been able to show the reasons behind this noted increase in prevalence of osteoarthrosis. Undoubtedly, the main reason has been the demographic shift towards older generations during the last decades, but obviously the prevalence in each age group has increased as well.1 In addition, generally accepted satisfactory criteria for osteoarthrosis are still lacking, and there has been variation from study to study in the criteria used to diagnose the disease.7-9

Osteoarthrosis commonly affects the knee joint,10-13 and the knee joint has been found to be one of the most usual targets of subjective rheumatic complaints,6 especially among women.14 There is, however, no reliable information available as to the actual occurrence and nature of knee osteoarthrosis and as to the extent and kind of examinations and treatment needed. This lack of reliable epidemiologic data and forecasts is an impediment to the planning of examination and treatment resources in knee arthritis and to an evaluation of the need for such measures.

The purpose of the present prospective study was to record and analyse all visits to physicians due to symptomatic knee osteoarthrosis over a period of one year, using a base population suitable in size for the purpose, in order to obtain reliable prevalence, incidence, and workload data, for the disease. The treatment already provided and the need for further specialised care were also examined.

Patient and methods

The project was based at the Orivesi Region Federation of Municipalities for Public Health Work in Finland. The size of the population in the area at the time of the study was 13 700; the Federation consists of the rural municipalities of Orivesi, Juupajoki, and Länselmäki with a total land area of 1228 km². At the time of the study 48% of the inhabitants were men and 52% women. Thirty six percent of them were under 30, 38% between 30 and 60, and 26% over 60. As services by private practitioners or medical specialists are not available in the area the inhabitants invariably seek both...
initial and further treatment primarily in their own community health centre. The Federation was therefore considered the best possible area for the research.

A record of visits paid due to symptomatic knee osteoarthrosis to the outpatient and inpatient units of the health centre was begun by the physicians (all experienced general practitioners) of the Federation on 1 July 1985. A research form designed for the purpose was used; for each visit the data on a total of 18 variables were recorded according to coding instructions specified in advance.

The diagnosis of knee osteoarthrosis was based on the patient's subjective evaluation, the clinician's objective evaluation, and an x-ray examination. The standardised subjective and objective criteria were pain at rest or on motion or night pain, or both; joint swelling or stiffness, or both; joint tenderness and crepititation; joint enlargement due to osteophyte outgrowths and capsular thickening; limited range of motion; and general discomfort of the affected knee. At least six of these criteria were required before acceptance in the study. An x-ray confirmation of the clinical diagnosis was required for every patient and was based on the classic radiological criteria of knee osteoarthrosis described by Kellgren and Lawrence, i.e., osteophytes, joint space narrowing, subchondral sclerosis or cysts, or both, and bone remodelling. At least three of these radiological criteria had to be fulfilled, before acceptance in the study.

Recording was continued for 12 months (1 July 1985–30 June 1986). The data on the research forms were transferred to a Dec 2060 computer at the University of Tampere and the results analysed using the BMDP-82 statistical software program.

**Results**

A total of 234 visits to physicians due to symptomatic knee osteoarthrosis were recorded in the area studied during one year, accounting for 0.63% of all consultations over this period. The number of patients was 152; there were thus an average of 1.5 visits per patient. The prevalence of the disease was 152/13 700 = 1.11%. Eighty two of these 152 patients were seeking medical help for their knee osteoarthrosis for the first time, giving an incidence of 0.60%. The prevalence of symptomatic knee osteoarthrosis for different age and sex groups is presented in Table 1. The age classification used was the same as that used by the central statistical office of Finland and by some previous studies of knee osteoarthrosis. The prevalence of the disease was 0.45% for men and 1.72% for women.

The osteoarthrosis affected the right knee in 40% of patients, the left in 22%, and both knees in 38%. The distribution of the visits over the year is shown in Fig. 1. Visits were somewhat, but not significantly, more common in the spring and summer months (April to September) than in the autumn and winter (November to March).

An x-ray examination of the knee was often carried out or arranged during the visit, confirming the clinical diagnosis. Most new patients (71%) had an x-ray examination at their first visit, and for the others it was arranged later on. Other further examinations were much less common; laboratory tests were needed in 6% and a diagnostic knee aspiration in 4% of the visits.

The modes of treatment most often used, are, presented in Table 2. Some patients required more than one treatment, and all were recorded. The most common treatments were non-steroidal anti-inflammatory pain medication (52% of visits), various types of physical therapy (24%), thigh muscle exercise (23%), and intra-articular or intramuscular injections of glycosaminoglycan.

polysulphate (21%). Intra-articular corticosteroid injections were not used.

Most patients (83%) needed no sick leave as they were pensioners. For the patients still working leave was unnecessary in 44% of the cases. The length of the leave was usually one to four weeks (33%) or less than a week (20%). A sick leave of more than one month was prescribed in 3% of visits.

The further care provided for the patients with knee osteoarthrosis is shown in Table 3. For one out of four visits the attending physician decided that no further care by physician was needed at that time. Five patients (2%) were referred for surgical consultation for assessment of the need for osteotomy or arthroplasty.

Total 234 100

As is the case with other diseases of the musculo-skeletal system, the epidemiological prevalence of osteoarthritis of the knee clearly depends on the age and occupational structure of the population studied. Orivesi, Juupajoki, and Längelmäki are typical Finnish rural municipalities in which agriculture is one of the principal means of livelihood, and the mean age of the population is high. In terms of the country as a whole the prevalence and incidence of knee osteoarthrosis obtained in the present study are evidently too high as a proportion of the population engaged in agriculture has been found to be affected with osteoarthritis more often than other occupational groups, and as this disorder becomes more prevalent with age, the incidence of knee osteoarthrosis (19.0%) is essentially the same as the prevalence (20.0%).

On the other hand, it should be remembered that all patients with osteoarthrosis do not seek medical attention even when suffering from severe symptoms. According to a report by Sievers et al., in Finland the condition of approximately 75% of the patients with arthrosis is continuously followed up. In 10% of cases there is no follow up despite the patients desire for it, and in 15% of patients the follow up is either desired or carried out.

In addition, when considering the results of studies of osteoarthrosis it should be remembered that there are always some cases whose subjective and clinical signs are similar to those of this disease, but in which the pathological process is actually something else e.g., chondromalacia, meniscal degeneration, etc. To minimise this problem radiological verification of knee osteoarthrosis was required in every case. In addition, before the study the physicians discussed the diagnosis and differential diagnosis of the disease.

The populations and the criteria for diagnosis of knee osteoarthrosis vary from survey to survey. According to Nordkild and Sonne-Holm most population studies of the disease (e.g. refs 20, 21) have used different, and often only subjective and/or clinical criteria to make the diagnosis, and therefore the prevalence values have varied considerably. For example, the prevalence of knee osteoarthrosis for women between 55 and 74 years of age seems to vary from 8-0% to 31-6% (median 19-0%).

In this prospective study we set out beforehand to avoid the above strict subjective, clinical, and radiological criteria (see ‘Patients and methods’) of knee osteoarthrosis, which had to be met before acceptance in the study. All the patients accepted sought medical help for their knee problem diagnosed as osteoarthrosis, and thus only symptomatic knees were actually recorded. This explains why our prevalence values for knee osteoarthrosis were low, for instance for women between 55 and 74 years the prevalence was 19.0%.

**Discussion**

Treatment for knee osteoarthrosis was sought by 1-11% of the population of the area over a period of one year, and the incidence of new patients (patients visiting the physician for the first time because of the knee arthritis) was 0-60%. Visits due to knee osteoarthrosis comprised 0-63% of all consultations with physicians.

The populations and the criteria for diagnosis of knee osteoarthrosis vary from survey to survey. According to Nordkild and Sonne-Holm most population studies of the disease (e.g. refs 20, 21) have used different, and often only subjective and/or clinical criteria to make the diagnosis, and therefore the prevalence values have varied considerably. For example, the prevalence of knee osteoarthrosis for women between 55 and 74 years of age seems to vary from 8-0% to 31-6% (median 19-0%).

In this prospective study we set out beforehand to avoid the above strict subjective, clinical, and radiological criteria (see ‘Patients and methods’) of knee osteoarthrosis, which had to be met before acceptance in the study. All the patients accepted sought medical help for their knee problem diagnosed as osteoarthrosis, and thus only symptomatic knees were actually recorded. This explains why our prevalence values for knee osteoarthrosis were low, for instance for women between 55 and 74 years the prevalence was 19.0%.
Occurrence of knee osteoarthrosis

3-44%. We feel that these prevalence values are clinically the most useful as these numbers are the most important for planning the examination and treatment resources in knee osteoarthrosis and in the assessment of the future need for such services.

As in other population studies, more women than men were included here, and the prevalence of the disease in women was also higher than in men (Table 1). The reasons for this female majority remain unknown, but a speculative link can be drawn between women with osteoarthrosis and obesity. Thus approximately twice as many Finnish women over 50 are obese (34%; overweight by \( \geq 20\% \)) than in the comparable group of Finnish men (16%). Obesity has been found to be associated significantly with knee osteoarthrosis.

Arthrosis occurred 1-8 times more often in the right knee than in the left. The magnitude of this disproportion conforms closely with the findings of Takala et al that in women hip (1-8 times) and knee (1-5 times) pains are considerably more common on the right side. The difference is even more apparent in rheumatic symptoms of the upper extremity, in which the continuous or repeated workloads of the right hand have been suggested as the most probable aetiological factor of right sided dominance. Despite the right sided dominance of symptomatic knee osteoarthrosis in this study it is very difficult to show that the right side of the lower extremities is involved in greater stress during life. This question remained unsolved and open to speculation.

Many of the patients received more than one form of treatment at the same time. The common use of glycosaminoglycan polysulphate injections was somewhat surprising, but may reflect the lack of any other curative mode of treatment of this disease. Glycosaminoglycan polysulphate has produced good short term results in the prevention of the deterioration of knee osteoarthrosis, but more evidence is needed before it can be accepted as the drug of choice in the treatment of this disease.

In 6% of cases the attending physician considered knee surgery (osteotomy, arthroplasty) necessary, but only one third of patients were actually referred for orthopaedic consultation. This small number of consultations probably reflects more the general concept of only moderate results for surgical treatment in knee arthropathy rather than the real need for surgery. We predict that the good results achieved in total knee arthroplasties in recent years will lead to a considerable increase in the need for such consultations in the near future.
