Rheumatoid arthritis and gut related lymphocytes: the iteropathy concept

P SHELDON

From the Department of Microbiology, Medical Sciences Building, Leicester

The aetiology of rheumatoid arthritis (RA) remains unknown. The involvement of the gut in reactive arthritis (ReA) and of the genitourinary system in Reiter's syndrome (RS), though recognised, is poorly understood. Distribution of phlogistic products via Batson's plexus has been suggested to account for the distribution of involved joints in these conditions.¹ Ankylosing spondylitis (AS) too has been associated with gut bacteria, including *Klebsiella pneumoniae*.^{2,3} It is possible that sulphasalazine, for which efficacy has been claimed in all these conditions,⁴⁻⁶ may mediate its effects by immunosuppression of the gut associated lymphoid tissue (GALT). This is because only at concentrations above those found in the blood stream is it immunosuppressive *in vitro*.^{7,8} If this also applies *in vivo* it opens up a whole new vista of possibilities regarding the aetiopathogenesis of these disorders.

The gut is a lymphoid organ at the heart of the secretory immune system, which is known to be involved in immune protection at mucosal surfaces and is largely mediated by IgA. It also includes certain other sites, however, which, though not strictly mucosal, have functions that are anatomically and functionally close. These include the salivary, lacrimal, and mammary glands. There is a reasonable body of evidence to indicate that these sites are normally colonised by lymphocytes or plasma cells, or both, that have seeded there from GALT,⁹⁻¹³ which is regarded as the major component of the mucosa associated lymphoid tissue. Mucosa associated lymphoid tissue comprises certain other sites, including the bronchi associated lymphoid tissue and the genitourinary tract lymphoid tissue. Homing tendencies of lymphocytes appear to be determined by adhesins,¹⁴ detectable using monoclonal anti-

bodies, the cells emerging within the lymphoid tissues at sites termed high endothelial venules.^{15,16} It has, on good authority, been stated that high endothelial venules are not present in mucosal tissues outside of GALT.¹⁷ Yet they have also been demonstrated in synovial membrane.¹⁸ In addition, IgA rheumatoid factor has been demonstrated in synovial membrane plasma cells, though the predominant class of antibody is IgG.¹⁹ It has also been demonstrated in synovial fluid, particularly high levels having been found in Sjögren's syndrome,²⁰ and in saliva of patients with RA and with Sjögren's syndrome.²¹ The serum and salivary IgM rheumatoid factor activities were more closely correlated than were the corresponding IgA rheumatoid factor levels, suggesting local production in salivary gland. The predominance of the polymeric as distinct from the monomeric form of IgA rheumatoid factor, whether as found in synovial fluid²⁰ or in synovial cell supernatants *in vitro*,¹⁹ bears testimony to the likely mucosal origin of the producing cells.

These findings imply the existence of a link between GALT and synovial membrane. Thus it may be suggested that gut lymphocytes, which have been shown to home physiologically to lacrimal or salivary glands, or both, in health, may, for reasons as yet not understood, do so pathologically giving rise to the sicca syndrome. Should they emerge solely in synovial membrane, RA might ensue, as a consequence perhaps of response to a cross reacting antigen. This may have been initially encountered in the intestinal lumen or wall, e.g., a component of bacterial cell wall that possesses epitope similarity with articular cartilage.²² Should they emerge at both sites, Sjögren's syndrome would be the result.

Another intriguing and well recognised fact in RA is the amelioration of the disease in many women during and for several months after pregnancy. During this time it has been shown that lymphocytes home to mammary gland and produce IgA that is

protective to the newborn infant. This homing is hormone dependent.²³ Immunohistological studies of lactating human mammary glands have shown densities of IgA producing cells of 65–70/mm² compared with approximately 60/mm² for normal parotid glands, 120/mm² for submandibular glands, 460/mm² for lacrimal glands, and 516/mm² for colonic mucosa. Far fewer produced IgG.²⁴ The overall number of plasma cells is far higher in the lactating than the resting breast.²⁵ Thus it seems reasonable to suggest that some of the IgG and much of the IgA synthesis that is known to take place in active rheumatoid synovial membrane may also take place (physiologically) in mammary gland. In other words the breast tissues of a pregnant patient with RA may compete with other mucosa associated lymphoid tissue, the net effect being the diversion of some of the cells that would otherwise home to the joints. A similar though less well characterised phenomenon may occur in placenta, where lymphocytes have been detected between decidual cells. With the aid of a recently described monoclonal antibody, HML-1, which recognises a novel membrane molecule present on intestinal intraepithelial lymphocytes, it has been shown that breast lymphocytes and one third to one fifth of these placental lymphocytes are positive.²⁶ Thus one may imagine the breast and placenta selectively depleting lymphocytes that would otherwise participate in the rheumatoid process within joints, a technique that bears a certain similarity to the depletion achieved by thoracic duct cannulation and drainage. It will be remembered that a large proportion of thoracic duct lymphocytes will have come from GALT en route to the mesenteric vasculature. Thoracic duct cannulation and drainage have been applied with some benefit in the management of intractable RA.²⁷ Interestingly, infusion of live thoracic duct lymphocytes from a patient with RA into her joints produced inflammation, but not when killed thoracic duct cells were employed.²⁷

One may naturally feel keen to try out HML-1 on lymphoid infiltrates seen in chronically inflamed synovial membranes, be they from RA, ReA, RS, or AS. The answer would be intriguing whatever the result. Should these cells be positive, this would be strong evidence of their origin from intestinal epithelium or lamina propria. Should they be negative, this could be interpreted as evidence of their origin from pre-intraepithelial lymphocytes or pre-lamina propria lymphocytes, i.e., they could have originated from Peyer's patches, which possess few HML-1 positive cells, or from mesenteric nodes. Their itinerary would have taken them through the thoracic duct, the blood stream, and then via high endothelial venules to synovial membrane, instead

of continuing via mesenteric vessels to the gut epithelium or lamina propria.

A difficulty arises through the fact that most lymphocytes in the synovial infiltrates in rheumatoid arthritis have been shown to consist of CD3+, CD4+ cells,²⁸ whereas most intraepithelial lymphocytes are CD3+, CD8+.²⁶ This does not apply to all GALT, however. Indeed the Peyer's patches and mesenteric lymph node cells are predominantly CD3+, CD4+.¹⁷ Another question is that of HLA-DR expression. This is prominent in the rheumatoid synovium²⁹ and nodule.³⁰ HLA-DR is also expressed on normal intestinal villous epithelium.³¹ Enhanced expression has been found in coeliac disease and dermatitis herpetiformis,³² ulcerative colitis, and Crohn's disease.³³ The discrepancy in degree of expression of HLA-DR in normal intestine and rheumatoid synovium cannot as yet be explained. Studies of HLA-DR expression in rheumatoid intestine might prove interesting, however, as the rheumatoid gut may not be as normal as has been assumed.³⁴

If we include the synovial membrane as part of the secretory immune system then the pattern of involvement of seemingly unrelated tissues within this system falls into place. It is difficult otherwise to imagine how an antigen itself would specifically select out these sites, but easier to construe that some primary fault in the migratory behaviour of lymphocytes operating within the secretory immune system could result in pathological sequelae at various points within the system. Such an abnormality may be viewed as an 'iteropathy' (iter—journey). Further studies into extrinsic and genetic factors affecting the itinerant proclivities of gut related lymphocytes may yield useful information regarding the aetiopathogenesis of rheumatoid arthritis and Sjögren's syndrome as well as the seronegative arthritides.

Dumonde has stated 'It is our view that lymphocyte activation products such as the lymphokine factors regulate the balance between inflammatory surveillance and adjuvant function of the cellular immune response by acting on cell co-operation or by controlling the traffic of lymphoid cell populations through critical regions of lymphoid and vascular tissue'.³⁵

The above arguments are in agreement with these remarks, except that the role attributed by Dumonde to lymphokines may in iteropathies be ascribed to exogenous agents. The iteropathy concept is intended to provoke thought about intestinal lymphocyte itineraries and the circumstances that may disturb them. These may include diet. As an example, vitamin A deficiency or protein-calorie malnutrition in rats have been shown to impair

localisation of mesenteric lymphoblasts following adoptive transfer.³⁶ Another candidate would be gut infection as seen in ReA. In either case the pathological process would be deemed to commence as a result of an iteropathy, the subsequent pathological events being dependent upon the initiating cause. In one scenario the antigen would gain entry to the joint as a passenger bound to a lymphocyte that it had rendered iteropathic, e.g., chlamydia (J Dixey *et al.*, unpublished data) or parvovirus.³⁷ In another scenario the iteropathy could be induced within the GALT by an extrinsic antigen, e.g., bacterial cell wall, and the subsequent events within the joints could possibly be the result of cross reactivity.

Yet another version that has a certain appeal concerns the interaction of microbial products and HLA antigens. In AS the HLA-B27 antigen has been shown to possess receptor properties for the 'modifying factor' released by certain plasmid infected enteric bacteria.³⁸ Might this modifying factor also modify the subsequent itinerant properties of HLA-B27+ GALT cells? If this were so it would raise similar questions for other arthropathies once the principle was established.

All these scenarios assume the lymphocyte itself to be iteropathic. An alternative possibility is that the iteropathy is the result of qualitative changes in high endothelial venules induced by these antigens. In this context it is of interest to note that several agents, including bacterial lipopolysaccharide, stimulate lymphocyte-endothelial cell adhesion in tissue culture.³⁹ This, however, leaves unexplained how they reach the high endothelial venules and why they should affect such seemingly unrelated sites. Thus when the routes taken physiologically by GALT are known it requires less imagination to conclude that these lymphocytes should be the target of disease causing agents, rather than the end organs (i.e., the joints) characteristic of the ensuing disease.

Whatever the mechanism(s), the subject of lymphocyte traffic is at last receiving increasing attention.⁴⁰⁻⁴¹ It is to be hoped that if this should indeed prove to be the fundamental link between gut and joint pathology in these diseases more effective treatment will be forthcoming, particularly for RA. This will require us to focus our therapeutic endeavours on the iteropathy rather than the consequences of chronic inflammation.
