Measurement of joint inflammation in rheumatoid arthritis with indium-111 chloride

Robert H Shmerling, J Anthony Parker, William D Johns, David E Trentham

Abstract

Studies in the collagen and rabbit models of arthritis have indicated that indium-111 chloride \(^{(111m_{\text{In}}Cl)}\) scintigraphy objectively measures synovial inflammation. Indium-111 chloride scans, with imaging three days after 19 MBq intravenous injection, were performed on 21 patients with definite or classical rheumatoid arthritis (RA), all of whom were functional class II. Standard clinical indices of disease activity were recorded at the time of imaging by the same investigator, who was unaware of the results of joint scans. In addition, eight patients with severe osteoarthritis, four of whom were considered to need hip or knee joint replacement, were similarly scanned. In each patient 16 joints were graded as 0 to 5, based on increasing degrees of \(^{(111m_{\text{In}}Cl)}\) uptake, by a single investigator blinded to the patient’s diagnosis and clinical status. In the group with RA significant correlations were observed between individual joint uptake on scan and peripheral joints with swelling, joints reported to be painful, and joints with any abnormality on physical examination. In the group with osteoarthritis, joints positive on scan correlated with the presence of pain. A total scan score (sum of individual joint scores) was calculated for each patient. In the patients with RA values ranged from 0 to 42 with a mean (SEM) of 20.7 \((2.7)\) and correlated with the number of swollen joints and decreases grip strength. In the group with osteoarthritis the mean total scan score \((9.2 \pm 1.5)\), range \(3-14\) was significantly lower than in the patients with RA. These data show that \(^{(111m_{\text{In}}Cl)}\) scanning can measure joint involvement by RA.

Objective and non-invasive measurement of synovitis would be invaluable in assessing disease activity of patients with rheumatoid arthritis (RA). Traditional methods of grading synovitis, such as the number of swollen or painful joints, are subjective and may not reflect changes in this disease. Currently available scintigraphic techniques, such as technetium-99m pertechnetate, have been advocated for this purpose but have received criticism owing to difficulties with interpretation and non-specificity.

Other radiopharmaceuticals have been sought which might selectively identify inflamed synovium. The radiocations, gallium-67 \((^{67\text{Ga}}\)) and indium-111 \((^{111\text{In}}\)) have been proposed because they possess a high affinity for iron binding proteins. \(^{11\text{In}}\) Synovial iron is increased in RA, and a close correlation between the inflammatory infiltrate and synovial ferritin content has been described.

Gallium-67 has been investigated as a joint imaging agent in RA and shown, in a rabbit model of arthritis, to accumulate preferentially in the inflamed synovial tissue. Like \(^{67\text{Ga}}\) citrate, \(^{111\text{In}}\)Cl has favourable gamma emissions and a short half life of 2-8 days. \(^{111\text{In}}\) chloride readily identifies cells expressing transferrin receptors, which are uniform markers of cell division, and competes more specifically than gallium for the iron binding site of transferrin. Previous studies showed that \(^{111\text{In}}\)Cl radioimaging accurately defined the arthritic response of rats to immunisation with collagen. A comparison with technetium-99m dicarboxyphosphate-diphosphonic acid joint scanning in two patients with RA suggested that the \(^{111\text{In}}\)Cl joint scan more closely reflected their clinical status. Similar attributes were found for \(^{111\text{In}}\)Cl imaging in a rabbit model of antigen induced arthritis, where the histological severity of synovitis correlated closely with uptake. This study was conducted to evaluate further \(^{111\text{In}}\)Cl joint scintigraphy in patients with arthritis.

Patients and methods

PATIENTS

Twenty one outpatients fulfilling the American Rheumatism Association criteria for definite or classical RA and eight patients with clinical and radiographic features of severe osteoarthritis of the hips and knees were recruited from the rheumatology clinic at our institution. The patients with RA were concurrently receiving non-steroidal anti-inflammatory drugs (19 patients), oral methotrexate 7.5 to 15 mg weekly (nine patients), prednisone 10 mg or less daily (eight patients), and parenteral gold (three patients). The patients with osteoarthritis were receiving non-steroidal anti-inflammatory drug treatment and had not received intra-articular injections. No patients were receiving iron treatment.

EVALUATIONS

Informed consent was obtained from patients and the \(^{111\text{In}}\)Cl joint scintigraphy was carried out as previously described. Each patient received 19 MBq \(^{111\text{In}}\)Cl intravenously, which exposes the patient to 2-5 mGy of whole body radiation (equivalent to the radiation exposure of 10 chest roentgenographs). Sixteen joint regions (hands, wrists, elbows, shoulders, hips, knees, ankles, and feet) were imaged at three
days for five minutes in the late morning with an Anger scintillation camera interfaced to a computer. All views were anterior projections. Total scanning time was 30 to 45 minutes with total counts in joint regions of interest of 1000 to 5000. Ten percent windows were set to detect the 173 and 247 keV peaks of 111In. Data were stored in a 128×128 matrix. The stored computer images were analysed independently by two observers (JAP and WDJ), who were unaware of the patients’ diagnosis or clinical status. A value of 0 to 5 was assigned to each joint, depending on the degree of uptake, as follows: 0=negative; 1=probably negative; 2=probably positive; 3=positive, faint; 4=positive; 5=positive, marked. By summing each patient’s 16 joint scores, a total scan score was calculated. A computerised score was obtained from a ratio of the activity over the joint to that over an adjacent soft tissue region, after correction for background outside the patient.

At the time of imaging a full examination was made of all the patients with RA by one investigator (RHS). Clinical data were recorded without knowledge of scan results. The methods used were those developed by the cooperating clinics committee of the American Rheumatism Association and used in other studies. Grip strength was measured with the same folded sphygmomanometer after the cuff had been inflated to 20 mmHg. The degree of overall synovitis was graded as 0, 1, 2, or 3, according to a previously formulated scale. The time required to walk 15 m, the duration of morning stiffness, and the number of anti-inflammatory and analgesic tablets or capsules ingested daily were recorded. The patient’s global assessment of status was graded. For the patients with osteoarthritis the investigator conducted a chart review and an examination for diarthrodial joints with pain, swelling, or deformity. In both patient groups a joint was considered to be abnormal on examination if swelling, deformity, pain on palpation or passive motion, or a restricted range of motion was detected.

STATISTICAL ANALYSIS
Correlations between positive (score ≥2) or negative (score ≤1) scans and swelling, pain, or any abnormality on examination were calculated with the \( \chi^2 \) test of association. Correlations between total scan score and clinical disease variables were calculated with the Pearson product-moment correlation coefficient. Comparison between the mean total scan score of patients with RA and osteoarthritis was made with Student's two tailed \( t \) test. A \( p \) value of <0.05 was accepted as evidence of significance.

Results
All 21 patients with RA were judged to be fulfilment class II. Table 1 presents the other clinical characteristics of these patients and of the eight patients with osteoarthritis. Four of the eight patients with osteoarthritis had been advised to have hip or knee replacement, but none had undergone surgery. Figures 1–3 show examples of \(^{111}\)InCl\(_3\) scans.

A total of 444 joint regions from the patients with RA and osteoarthritis was considered by both observers to be visualised sufficiently well on scan to allow scoring. In 183 (41%) there was exact agreement in score. Disagreements by one to five grades occurred in 131 (30%), 70 (16%), 39 (9%), 20 (5%), and 1 (0.2%) joints respectively. Thus there was agreement within one score grade in 314 (71%) joints, and the two observers’ scores were highly correlated (\( r=0.72 \), \( p<0.0001 \)). Scoring of the ankles and feet differed markedly between observers, however. One observer had an average score of 1.38 for the ankles and feet, while the other had an average score of 3.00. Fourteen of the 21 disagreements by four or five score units occurred in the ankles or feet.
The computerised score was difficult to implement owing to the varying background adjacent to the joint. An attempt was made to pick a representative region, but the computer calculations were heavily dependent on region selection. There was almost no correlation between the computer score and the subjective scan score, apparently because of background uptake. Subjective scan results depicted in the remainder of this paper, therefore, represent the readings of the senior radiologist (JAP).

**STUDIES IN RA**

Table 2 compares clinical findings and $^{111}$InCl$_3$ scans in the patients with RA. Of 248 individual joints, excluding the shoulders and hips, 77 were considered to be swollen. Forty-four (57%) of the swollen joints were positive on $^{111}$InCl$_3$ scan. Of the 171 peripheral joints without swelling, 47 (27%) were positive. The overall agreement (positive scan with swelling present and negative scan with swelling absent) was 68%. The correlation between joint swelling and scan results was significant ($\chi^2=18.8, p<0.001$). Similarly, a highly significant ($\chi^2=20.9, p<0.0001$) correlation was observed between individual joints reported to be painful and considered positive on scan. This assessment included the shoulders and hips. The overall agreement between painful joints and scan results was 65%. Indium-111 chloride joint scanning also correlated with joints that were both swollen and described as painful ($\chi^2=35.5, p<0.001$) and with joints that showed abnormalities on physical examination ($\chi^2=6.1, p<0.02$). The overall agreement was 73% for swollen, painful joints and 55% for abnormal.

* As described in table 2, analysis was performed on a total of 332 joints.
joints. Table 3 shows the number of positive scans in the various joints. There was no significant association between the computerised scores and any of the clinical variables.

The $\chi^2$ test of association was also used to examine relations between clinical variables. After exclusion of pain in hips and shoulders joint pain was compared with swelling. Although these clinical variables were associated with one another ($\chi^2=11.2, p<0.001$), only 50 of 105 (48%) painful joints were also swollen. The overall clinical agreement between pain and swelling was 66%.

STUDIES IN OSTEOARTHRITIS

Among the eight patients with osteoarthritis, nine (30%) of the 30 joints reported as painful were positive on joint scan; of the 98 asymptomatic joints, nine (9%) were positive. The overall agreement was 77%. There was a significant ($\chi^2=8.2, p<0.01$) correlation between joints positive on scan and the presence of pain. Positive scans were not significantly associated with abnormalities on joint examination or the presence of swelling, which was rare. Joints positive on scan consisted of eight wrists, four knees, two hands, two hips, and two shoulders. It was not possible to distinguish between carpometacarpal and radiocarpal uptake in the positive wrists.

TOTAL SCAN SCORE

The mean (SEM) total scan score in the patients with RA was 20.7 (2.7) (range 0–42), while the mean score in the patients with osteoarthritis was 9.2 (1.5) (range 3–14). The difference between these means was significant ($p<0.001$). In the group with RA the total scan score correlated with the number of swollen joints (fig 4) and was inversely related to grip strength (fig 5). In neither group was there a significant association between the total scan score and other clinical or demographic variables measured.

Discussion

In this study joint uptake of intravenously administered $^{111}$InCl$_3$ correlated significantly with conventional clinical measures of arthritis in a group of patients with RA who had varying duration of disease, pattern of joint involvement, and type of treatment. These findings support the suggestion that transferrin receptors are abundant in inflamed synovium and may indicate an important role for iron in the pathogenesis or perpetuation of the chronic synovitis seen in RA.

The ability of $^{111}$InCl$_3$ to identify clinically active joints of patients with RA may make it a useful technique to detect, quantify, and monitor synovitis in this disease, and possibly in other conditions of chronic joint inflammation.

The sensitivity and specificity of diagnostic scanning with $^{111}$InCl$_3$ are difficult to calculate from this study. As there is no standard by which the cause of symptoms or signs of joint inflammation may be determined, even in patients meeting criteria for RA, we cannot rule out subclinical rheumatoid synovitis in a joint that is asymptomatic but positive on joint scan. Similarly, joints that were symptomatic or swollen but negative on $^{111}$InCl$_3$ scan may represent poor sensitivity, or may indicate that a process other than rheumatoid synovitis explains the clinical findings. The presence of pain and swelling correlated imperfectly with one another, again making it difficult to estimate the accuracy of $^{111}$InCl$_3$ joint scanning.

Patients with osteoarthritis generally had negative $^{111}$InCl$_3$ joint scans. The positive joint scans in these patients may represent subclinical inflammation ('inflammatory osteoarthritis') or may, alternatively, represent false positive results.

There was total disagreement (disagreement by four or five categories) between observers in 5% of readings. More than half of this disagreement was found to be due to a marked difference in interpretations of readings for ankles and feet. Caution also had to be used in interpreting shoulder and hip scans owing to the
occasional presence of contiguous bone marrow uptake. New criteria have been developed for this group of patients, which will be evaluated in further studies in an attempt to improve the precision of interpretation.

Scintigraphic experience with intravenously administered $^{111}$InCl$_3$ in patients with osteomyelitis has shown that this technique accurately detects infection. Interestingly, positive scans without infection were encountered in two patients with inflammatory arthritis.

Although this study is the first systematically to relate clinical features of RA and osteoarthritis to $^{111}$InCl$_3$ scan results, it poses the limitations commonly associated with scintigraphy. As synovial fluid or biopsy material was not obtained from the joints of these patients we cannot be certain that uptake indicated inflammation. We have not repeated scans on individual patients to analyse whether changes in joint scans correlate with alterations in clinical status or treatment, nor have we followed up patients for long enough to know whether joints considered false positive on scan will eventually develop clinical disease.

The clinical evaluation of disease activity in RA is hampered by a lack of objective measures. Although the technique is sufficiently safe and the results in this study are promising, they must be considered preliminary. Further analysis will be required to determine the true value of $^{111}$InCl$_3$ joint scanning in individual patients with RA.

The authors wish to thank Ms Barbara Brown for manuscript preparation. This work was supported in part by USPHS research grants AR-38331 and AM-36356, the Charles A Dana Research Institute, and the Harvard-Thorndike Laboratory of Beth Israel Hospital. Data analysis was performed on the Core laboratory computer.
