The role of angiogenesis in rheumatoid arthritis: recent developments

Alisa Erika Koch

Rheumatoid arthritis (RA) is characterised by synovial tissue leucocyte ingress and angiogenesis, or new blood vessel growth. The disease is thought to occur as an immunological response to an as yet unidentified antigen. Even in early RA, some of the earliest histological observations are blood vessels. A mononuclear infiltrate characterises the synovial tissue along with a luxuriant vasculature. Angiogenesis is integral to formation of the inflammatory pannus and without angiogenesis, leucocyte ingress could not occur.

Angiogenesis is regulated by a complex set of inducers and inhibitors. In this paper we will present representative examples of both angiogenesis inducers and inhibitors that may regulate RA neovascularisation (fig 1). In inflammatory states like RA, angiogenesis inducers outweigh angiogenesis inhibitors.

Angiogenesis inducers

ENDOGLIN AS AN ANGIOPGENIC MEDIATOR

There are a number of angiogenesis inducers that may play a part in RA. Among these are endoglin, an endothelial glycoprotein, which contains an arginine-glycine-aspartic acid (RGD) motif, and also acts as an adhesion molecule. Endoglin is a receptor for transforming growth factor β. Mice lacking the endoglin gene die from defective vascular development. We have shown that endoglin is upregulated in RA synovial endothelial cells compared with normal synovial tissue endothelial cells.

VASCULAR ENDOTHELIAL GROWTH FACTOR (VEGF)

An angiogenic mediator that has attracted much attention recently is VEGF, which is an endothelial selective growth factor. VEGF induces vascular permeability as well. In human RA, several groups have described VEGF in the joints and serum of RA patients. VEGF is inducible by hypoxia, which may occur in the inflamed joint. Hypoxia inducible factor-1 (HIF-1), which is made of HIF-1α, and hydroxycarbon nuclear translocator (ARNT), controls many transcriptional responses to hypoxia by binding to hypoxia response elements of target genes like the VEGF gene. In RA patients treated with anti-tumour necrosis factor α (TNFα), vascular deactivation occurs so that serum levels of VEGF fall along with clinical improvement. A number of groups presented at the 1999 National American College of Rheumatology (ACR) meeting on the regulation of VEGF production by synovial fibroblasts, mainly from patients with RA (fig 2). Not only do cytokines like interleukin 1 (IL1) and TNFα induce fibroblast expression of VEGF, but so does engagement of CD 40 ligand. Bone morphogenetic proteins (or BMPs), which induce formation of cartilage and bone, and seem to downregulate IL1 induced VEGF production. VEGF induces endothelial decay accelerating factor (DAF), which is cytoprotective against activated complement and may regulate endothelial proliferation and angiogenesis.

Similarly, the role of VEGF has been examined in animal arthritis models. In collagen induced rats, a reduction in arthritis disease severity by angiogenesis inhibitors results in reduced serum levels of VEGF. Administration of the fungal derivative TNP-470 in rodent arthritis leads to attenuated arthritis and serum VEGF production. Administration of the VEGF receptor soluble f1-l in mouse collagen induced arthritis results in attenuated arthritis. These results indicate that modulation of angiogenesis may alter arthritis, at least in animal models. Hence, VEGF is probably an important mediator of angiogenesis in the RA joint.
Chemokines as angiogenic mediators

Among other important mediators of angiogenesis are chemokines. Most chemokines are low molecular weight (8 kDa to 10 kDa) proteins that are predominantly known for their ability to recruit leucocytes. Chemokines are divided into the C-X-C, CC, and C-X3-C families based on the presence or absence of an amino acid, X, between a pair of cysteine residues near the amino terminus of the protein. In collaboration with Dr Robert Strieter, Peter Polverini, and Steve Kunkel, our group found that monocyte/macrophage derived interleukin 8 (IL8), a prototype of the C-X-C chemokine subfamily, was angiogenic. This factor seemed important in that synovial tissue macrophage derived chemotactic activity for endothelial cells in vitro and angiogenesis in vivo was significantly decreased if IL8 was immunodepleted. In general, chemokines like IL8, of the C-X-C class containing the amino acid E-L-R motif are angiogenic, while those lacking this motif are angiostatic. Exceptions to this generalisation exist in that the C-X-C chemokine stem cell derived factor-1, which lacks the E-L-R motif is angiogenic.

We have recently shown that fractalkine is the first chemokine described of the CXC class to mediate angiogenesis. Fractalkine is termed for its fractal geometry and is the sole member of the CXC class of chemokines. It contains a chemokine motif atop a mucin-like stick, the so called chemokine on a stick (fig 4). Fractalkine is a unique chemokine in that it can also act as an adhesion molecule when cell bound. Fractalkine induces endothelial tube formation on the matrix Matrigel in vitro. Similarly fractalkine induces angiogenesis in Matrigel plugs implanted in mice in vivo. When fractalkine is immunodepleted from RA synovial fluids, the ability of these synovial fluids to chemotact endothelial cells, a facet of the angiogenic response in vitro, is decreased. Hence, chemokines are probable contributors to RA angiogenic activity.

Soluble adhesion molecules as angiogenic mediators

Endothelial cells express soluble adhesion molecules, particularly upon cytokine stimulation. Cellular adhesion molecules can be shed from the cell surface and secreted. The function of these soluble adhesion molecules is unclear. A prevailing paradigm was that these molecules might serve an anti-inflammatory role by binding leucocytes, thus preventing...
The role of angiogenesis in rheumatoid arthritis

Angiogenesis refers to the growth and formation of new blood vessels, which is essential for the supply of oxygen and nutrients to tissues. In rheumatoid arthritis (RA), angiogenesis plays a critical role in the repair and regeneration of inflamed synovial tissue, which can be seen as new blood vessels sprouting and growing into the synovial fluid. This process is mediated by various factors and receptors that interact with the endothelial cells lining the blood vessels.

Soluble 4A11 antigen (Le^x) is a key player in this process. It is recognized for its function as a blood group antigen but also serves as an endothelial angiogenic mediator. The antigen is rapidly cytokine inducible in vitro, being stored in cytokines and released upon activation. It is endothelial selective, indicating a role in cell homing to regions with angiogenic potential.

GLYCOCONJUGATES AS ANGIOGENIC MEDIATORS

Glycoconjugates, which are glycoproteins or glycolipids, are crucial in the regulation of angiogenesis. They are used by endothelial cells as adhesion receptors, which help in the adherence and migration of cells throughout the body. In RA, the presence of glycoconjugates is thought to be important in the induction of angiogenesis.

Antigens. Interestingly, these antigens are structurally related to the E-selectin ligand sialyl Lewis^x. Because of the angiogenic properties of soluble E-selectin, we hypothesized these endothelial antigens were released by activated endothelium and induced angiogenesis. Glucose analogues of these molecules or the glycolipids themselves induced a potent endothelial chemotactic response. Moreover, the glucose analogues are angiogenic in vivo in the corneal bioassays. mAb 4A11 abrogated the angiogenic responses. We reasoned that if these molecules mediated angiogenesis, they could be detected in clinical samples from RA patients. We found that soluble 4A11 antigen is increased in RA compared with OA serum and synovial fluid. These results describe a novel endothelium selective antigen that functions as an angiogenic mediator. As with the E-selectin and VCAM-1, it is probable that endothelial cells exposed to cytokines bear the 4A11 antigen, which is shed in the inflamed joint and mediates angiogenesis (fig 5).

Glycoconjugates (glycoproteins/glycolipids) have been known for some time to constitute the chemical basis for several blood group systems in humans and to act as adhesion molecules for microbial ligands, though no physiological role has been shown, for them until recently. A mAb MIA-15–15, detecting Le^y/Le^xH, inhibited the motility of tumour cells in vitro. As the potential of tumour cells for invasion is closely associated with motility, which seems to depend on specific glycosylation, it followed that patients bearing lung carcinomas identified by mAb MIA-15–15 had a strikingly worse prognosis than those whose tumours were MIA-15–15 negative. The importance of glycoconjugates in the induction of autoimmunity was recently underscored by the finding that Helicobacter pylori, the microorganism involved in gastritis, ulcers, adenocarcinoma, and lymphoma of the stomach, expresses Le^y/Le^xH, which is also found in gastric mucin. Mice bearing hybridomas making H pylori induced anti-Le antibodies developed gastritis, pointing to a mechanism by which H pylori participates in “molecular mimicry”. Hence, antibodies directed against H pylori Le^y result in gastritis via an autoimmune reaction directed against gastric mucin Le^y. In diseases such as RA, the inciting agent is unknown. Thus, it is possible that Le^y/H may also trigger a “molecular mimicry” immune reaction in inflammatory angiogenic sites such as RA.

There exists a hypothesis that while endothelium is quiescent for weeks or longer, endothelial cells must also require a mechanism of storage of “preformed” regulators of angiogenesis that are capable of inducing new capillary growth within hours in response to angiogenic stimuli, such as those found in a wound or an inflamed synovial tissue. Despite this hypothesis, with the possible exception of bFGF, examples have not been described for angiogenesis inducers. The rapid cell surface expression of Le^y/H may fit this paradigm. However, an alternative scenario concerning the regulation of angiogenesis by inducers and inhibitors may be that “structural” mimicry plays a part.
Hence, for instance, a search based on crystal structure revealed that the angiogenic inhibitor endostatin was most homologous to the angiogenic mediator E-selectin (Bjorn Olsen, data presented at the Angiogenesis in Cancer Meeting, Orlando, FL 24-28 January 1998). It is probable that in an RA joint Lea/H may be stored for expedient use during times of active inflammation and subsequent angiogenesis.

Angiopoietins and ephrins control vascular growth and development

Though as yet not examined in RA, the angiopoietins are increasingly being recognised as modulators of vascular development that may eventually play a part in vascular targeting. Angiopoietin-1 participates in the maturation of blood vessels while angiopoietin-2 is a natural antagonist of angiopoietin-1. Interestingly, both angiopoietin-1 and -2 bind the tyrosine kinase receptor Tie2. In vascular development, membrane bound ephrin-B2 marks future arterial cells and its Eph-B4 receptor marks future venous cells. If either the angiopoietin-1 gene or the ephrin-B2 gene are deleted in mice, angiogenic remodelling is perturbed. A new aspect of angiogenesis has recently been explored. Angiopoietin-1 overexpressing mice form blood vessels that are not leaky. This is in sharp contrast with VEGF overexpressing mice, who form leaky vessels. Moreover, overexpression of angiopoietin-1 results in resistance to leakage caused by inflammatory agents in mice. As we learn more about the process of vessel growth and development, it is tempting to speculate that in the future certain types of angiogenic factors may be used to “harden” vessels against the effects of inflammatory mediators.

Angiogenesis inhibitors

PARADIGM OF INHIBITORS RESIDING WITHIN LARGER PROTEINS

The regulation of angiogenesis is likely to result from a delicate balance of angiogenesis inducers and inhibitors (fig 1). Currently, a number of angiogenesis inhibitors have been identified, some of which fit neatly into emerging paradigms. One paradigm mentioned above is that angiostatic activity often resides in portions of larger common proteins that may or may not themselves be angiostatic. Examples of this include many molecules thought to play a part in RA pathogenesis, like thrombospondin, fibronectin and propeptides of type II collagen, platelet factor IV, and fragments of epidermal growth factor. Other mediators fitting this paradigm are: the 29 kDa fragment of fibronectin, the 16 kDa fragment of prolactin, and angiostatin (a fragment of plasminogen), among others.

THROMBOSPONDIN AS AN ANGIOGENESIS INHIBITOR

The idea that endothelium is quiescent for long periods of time and yet can be induced to sprout new capillaries in a matter of hours in response to an angiogenic stimulus, suggested that angiogenesis regulators might be stored for expedient use. The first indication of this paradigm was described by Dr Noel Bouck and coworkers, who found that a non-tumorigenic hamster cell line became tumorigenic with a mutation that inactivated a tumour suppressor gene. The inhibitory activity was found to be a fragment of the adhesive glycoprotein thrombospondin-1 whose expression was linked to the presence of a tumour suppressor gene. Thrombospondin seems to act via inducing endothelial cell apoptosis. Recently metalloproteases have been found using molecular techniques, and are even more potent angiogenic inhibitors than thrombospondin. We were unable to show an effect of inhibiting arthritis or angiogenesis in a rat model of adjuvant induced arthritis.

ANGIOSTATIN AS AN ANGIOGENESIS INHIBITOR

Another inhibitor of angiogenesis termed “angiostatin” has been identified in some very elegant studies by Dr Judah Folkman’s group. This factor is a potent inhibitor of tumour growth. Angiostatin is a fragment of the clotting factor plasminogen. Plasminogen itself is not angiostatic. This factor acts by depleting energy required for blood vessel growth by binding ATP-synthase and induces endothelial cell apoptosis by activating focal adhesion kinase. The role of angiostatin in RA has not yet been defined.

ENDOSTATIN AS AN ANGIOGENESIS INHIBITOR

Likewise, endostatin, an angiogenesis inhibitor produced by mouse haemangioendothelioma cells, is a fragment of collagen type XVIII. Thus, the fact that abundant components of the circulatory system such as fibrinogen and plasminogen can be converted to potent angiostatic factors suggests a new form of regulation by proteases, such as serine proteases to specifically release these molecules from their parent molecules. One might envision that in the case of RA, these inhibitors might be present, but downregulated.

Can angiogenesis regulation help us in the treatment of patients with RA?

ANGIOGENESIS INHIBITORS RELEVANT TO THE RHEUMATIC DISEASES

Some of the endogenous and exogenous inhibitors of angiogenesis that have been identified to date include: a cartilage derived factor, troponin, angiostatic corticosteroids, minocycline, fumigillin, thalidomide, chloroquine, sulfapyridine, methotrexate, penicillamine, thalidomide, ethylene, cyclosporin, cyclophosphamide, and plasminogen can be converted to potent angiostatic factors. Thus, the fact that abundant components of the circulatory system such as fibrinogen and plasminogen can be converted to potent angiostatic factors suggests a new form of regulation by proteases, such as serine proteases to specifically release these molecules from their parent molecules. One might envision that in the case of RA, these inhibitors might be present, but downregulated.

SHARK CARTILAGE: AN ANTI-ANGIOGENESIS AGENT

Shark cartilage contains a potent inhibitor of angiogenesis, accounting for its popularity in some circles as an unorthodox treatment for cancer. A cartilage derived inhibitor from bovine scapula has been described that is also an inhibitor of collagenase. Recently, a human cartilage derived angiogenesis inhibitor has been shown to be tropinin I, a protein responsible for regulation of muscle contractions. Like angiostatin, tropinin I acts by binding ATPase,
The role of angiogenesis in rheumatoid arthritis

thus depleting energy needed for blood vessel growth. Regardless of the source, it is intriguing that cartilage, which lies in juxtaposition to the inflamed RA synovium, may hold a key to the understanding of how one might inhibit the angiogenic process in the joint.

Fumagillin is an angiostatic compound discovered as a fungal contaminant on an endothelial culture dish that inhibited endothelial growth.97–99 Derivatives of this compound termed AGM-1470 or TNP-470 inhibit both angiogenesis and arthritis in rodent models.97–99 Interestingly, angiogenesis may also play a part in bone formation. TNP-470 inhibited ectopic bone formation induced by bone morphogenetic protein in mice.94 Fumagillin may be a potential therapeutic agent inhibiting arthritis and angiogenesis in RA.

Several angiogenesis modulating agents have recently been tried in rodent models of arthritis. These include taxol, thalidomide, and 2-methoxyestradiol. Thalidomide is an inhibitor of both angiogenesis, which may account for its teratogenic effects on limb bud formation, and TNFα.86–89 Thalidomide suppressed rat collagen induced arthritis but not via inhibition of the angiogenic cytokines TNFα or VEGF.89 Taxol, a chemotherapeutic agent, inhibited collagen induced arthritis in rats and inhibited synovial angiogenesis.89 2-methoxyestradiol treatment of collagen induced arthritis in mice resulted in a decrease in arthritis. In vitro, this compound inhibited proliferation of endothelial cells.90

Prostaglandins, such as prostaglandin E2, are potent mediators of angiogenesis.96,97 COX-2 inhibitors have recently been released and used for the treatment of RA. Not surprisingly, they have been shown to inhibit angiogenesis mainly in tumour models.90–95 It is quite possible that these modulators are also effective in reducing RA angiogenesis.

Sulfasalazine is commonly used in the treatment of a variety of diseases including RA. The active metabolite of sulfasalazine may be sulfapyridine. In one study, while sulfapyridine inhibited endothelial proliferation, sulfasalazine and 5 aminosalicylic acid metabolites did not.92 We have recently shown that sulfasalazine and sulfapyridine reduce endothelial proliferation as well as chemotaxis.92 Sulfapyridine can also inhibit phorbol myristate acetate (PMA) induced endothelial tube formation in vitro. We have also shown that sulfapyridine may mediate this effect by reducing endothelial IL8 production.

Therapeutic considerations

CAN ANGIogenic MARKERS HELP GUIDE TREATMENT IN RA?

Recently soluble CD 146, an endothelial cell adhesion molecule involved in leucocyte-endothelial interactions, was found to be upregulated in synovial fluids from patients with RA compared with traumatic injury.104 Patients with early RA had the highest values of this marker in their synovial fluid. Soluble CD 146 correlated significantly with the degree of morning stiffness, the number of tender joints, and the number of swollen joints.

In papers presented at the ACR meeting VEGF and bFGF were shown to be increased in RA compared with normal serum, especially in early erosive RA and in patients who had antibodies to Sa, an endothelial antigen, as well as to collagen.105 Serum VEGF is increased in early RA.106 Early RA synovial fluid VEGF and matrix metalloproteinase (MMP)-9 correlate with each other and with arthroscopic synovitis and vascularity scores.107 Evidence is mounting that markers of angiogenesis may help us assess early RA.

CAN ANGIOGENIC MARKERS PREDICT RA DISEASE OUTCOME?

Also at the ACR, meeting preliminary data using the Eudriss cohort study indicated that sVCAM-1 and CD 31 can predict disability and radiological changes in RA.108 Serum VEGF was associated with greater disease activity and soluble selectins were associated with increased disability. Hence, it is tempting to speculate that angiogenic markers may help guide us in RA treatment in the future.

WHAT DOES THE FUTURE HOLD IN ANGIOGENESIS MODULATION?

One might envision vascular targeting strategies. For targeting to be effective, it will be necessary to develop markers to assess the synovial vasculature. In addition to clinical markers of disease activity described above, various imaging techniques are being assessed for evaluating synovial vascularity. One such technique used in rat adjuvant induced arthritis is the use of a radiolabelled E-selectin binding peptide.109 Some imaging techniques already tried in humans include gadolinium-DTPA enhanced magnetic resonance imaging of RA joints, which correlates with blood vessel density as determined by synovial tissue histology.110 High resolution ultrasound is also new technique that has been tried for RA joint imaging.111 Using this technique, the investigators found that inactive versus active RA patients had increased vascularity.

Once strategies are developed for monitoring vascular therapies, and if vascularity is shown to be reflective of disease activity, it is probable that vascular targeting may become a reality. Possible strategies include viral vector targeted antiangiogenic gene treatment, as has been tried in animal models of tumour growth with angiostatin, the VEGF receptor flt-1, and the Tie2 angiopoietin-1 and 2 endothelial receptor.112–114 One may envision strategies like gene treatment with dominant negative VEGFR-1 mutants that prevent VEGF mediated effects on the vasculature. Another therapeutic avenue might be gene treatment with modulation of hypoxia response elements that become selectively activated under hypoxic conditions. Methods aimed at inducing vascular proliferation, perhaps by induction of apoptosis may be another potential strategy to disease modification.
