Comorbidity and lifestyle, reproductive factors, and environmental exposures associated with rheumatoid arthritis

Å Reckner Olsson, T Skogh, G Wingren

Abstract

Objective—To evaluate the influence of lifestyle, reproduction, and some external factors on the development of rheumatoid arthritis (RA) and to describe its comorbidity.

Methods—Cases were identified retrospectively from 1980 to 1995 at the University Hospital in Linköping, Sweden. The study comprised 422 cases and 859 randomly selected population referents. Data on possible aetiologial factors and comorbidity were collected by postal questionnaire.

Results—The response rates were 67% among cases and 59% among referents. A decrease in the occurrence of atopic allergy was seen in the cases (odds ratio (OR) 0.6, 95% confidence interval (CI) 0.4 to 1.0). There was a positive association between RA and insulin treatment (OR 10.2, 95% CI 1.7 to 60.8) in women, and women with a short fertile period had an increased risk of RA (OR 2.5, 95% CI 1.1 to 5.4). Current and previous smoking were associated with increased risks for RA in both sexes, and in men a dose-response relationship was found with number of tobacco pack years (p for trend <0.005). The risk for RA decreased with increasing level of education in both men and women. Increased risks were seen in men born into households with private wells (OR 2.8, 95% CI 1.5 to 5.2), residenitally exposed to mould (OR 4.6, 95% CI 1.1 to 20.2), or exposed to farm animals (OR 3.3, 95% CI 0.7 to 16.6). In women there were positive associations between RA and reporting a previous joint injury (OR 2.5, 95% CI 1.0 to 6.6) and prolonged exposure to hair dyes (OR 1.9, 95% CI 0.8 to 4.5).

Conclusions—RA, a disease with features of T helper 1 (Th1) dominated immune response, was inversely associated with atopic allergy, a Th2 dominated condition, while there were indications of a positive association with Th1 related diabetes mellitus. The results support a causal relationship between smoking and RA. The level of education was inversely associated with RA, while there was a positive association between RA and certain residential factors in men and a short fertile period in women.

Rheumatoid arthritis (RA) is a disorder of unknown aetiology. The susceptibility for RA probably varies between individuals as a result of genetic and hormonal factors, and the mechanisms underlying RA are complex and depend on a number of internal and external factors. RA has features of an organ specific autoimmune disease with a T helper 1 (Th1) dominated immune response, and it has been anticipated that an antigen driven immune response is required to perpetuate the disease, although the crucial antigen(s) have not been identified. Considering the functional dichotomy between Th1 and Th2 type responses, it is conceivable that other Th1 mediated autoimmune diseases could be over-represented in patients with RA whereas an inverse relationship could be expected between RA and Th2 mediated conditions. Indeed, previous studies have supported a positive association between RA and, for example, thyroiditis, and a negative association between RA and atopy.

Despite the female preponderance, oestrogen and progesterone seem to have a suppressive effect on RA disease mechanisms. The highest incidence of RA in women occurs after menopause when the levels of sex hormones decrease. Even so, the female preponderance is least pronounced in the older age group because of an increased incidence of RA in men which may be related to lower testosterone levels with increasing age. There are also indications of a primary hypoandrogenicity in both men and women with RA. Hypoprolactinaemia during breast feeding, for example, is known to stimulate Th1 mediated immunity, and a genetic linkage between human leucocyte antigen (HLA)-DR genes and genes regulating prolactin levels has been suggested. In rats the female preponderance for RA seems to be associated with a sex chromosome gene which may act together with female sex steroid hormones.

Possible external contributions to the disease process in RA include lifestyle factors such as smoking and alcohol, as well as infectious agents, occupational exposures, and exposure to pets. Furthermore, the relationship between RA and educational level, certain surgical procedures, and major life events has been studied.

The aim of this study was to evaluate the influence of lifestyle, reproductive, and environmental factors on the development of RA and to describe its comorbidity.
Methods

SUBJECTS

Medical records of patients attending the Division of Rheumatology at the University Hospital in Linköping in 1995 were used to identify prevalent cases of RA. Cases were required to fulfill the American Rheumatism Association (ARA) 1987 revised criteria for the classification of RA and to be aged 25–75 years during the study period which extended from 1 January 1980 to 30 June 1995. Four hundred and thirty two cases fulfilled the inclusion criteria.

The degree of recruitment of cases was likely to vary within the catchment area of the hospital since there are other smaller health care units in the most distant parts of the area. The study base was therefore defined by the postal zip codes of cases at the time of diagnosis for cases and at the year of enrolment for referents. When relevant, the material was analysed separately for men and women stratified into three age groups: 25–40, 41–55, and 56–75 years of age at the time of diagnosis for cases and at the year of enrolment for referents. When relevant, the material was also stratified into three smoking categories (non-smokers, past or present occasional smokers, and past or present regular smokers), and for some analyses stratification was also made for occupation, marital status, and socioeconomic status.

The results are presented for assessments of a priori hypotheses based on earlier findings from the literature. New associations are presented when the number of exposed subjects was at least 10 and the risk estimate was \(>1\). ORs from separate analyses of 83 men and 134 women who were rheumatoid factor (RF) positive are also shown. Never users of tobacco are regarded as unexposed and are presented in a separate report.22

Before analysis 10 cases and five referents who were found not to fulfill the inclusion criteria were excluded. Two referents had stated having RA which was diagnosed before their year of enrolment. The final study population therefore comprised 422 cases and 859 referents.

DATA ANALYSIS

The associations between RA and possible aetiological factors as well as comorbidity were evaluated by general principles for case-referent studies using the computer program EPI INFO (EPI INFO 6.04, Center for Disease Control and Prevention (CDC), USA). The material was analysed separately for men and women stratified into three age groups: 25–40, 41–55, and 56–75 years of age at the time of diagnosis for cases and at the year of enrolment for referents. When relevant, the material was also stratified into three smoking categories (non-smokers, past or present occasional smokers, and past or present regular smokers), and for some analyses stratification was also made for occupation, marital status, and socioeconomic status.

The results are presented for assessments of a priori hypotheses based on earlier findings from the literature. New associations are presented when the number of exposed subjects was at least 10 and the risk estimate was \(>1\) or \(<0.5\), or otherwise significantly different from unity. Analyses were performed on the association between the start of exposure and the year of diagnosis according to the ARA for cases, and the year of dummy date of onset for referents. When considered relevant, analyses were also performed to examine the association between start of exposure and year of onset of symptoms for cases. Exposures occurring after these dates were disregarded. To be regarded as exposed, subjects were required to have a minimum duration of exposure of 6 months.

SUBJECTS

Medical records of patients attending the Division of Rheumatology at the University Hospital in Linköping in 1995 were used to identify prevalent cases of RA. Cases were required to fulfill the American Rheumatism Association (ARA) 1987 revised criteria for the classification of RA and to be aged 25–75 years during the study period which extended from 1 January 1980 to 30 June 1995. Four hundred and thirty two cases fulfilled the inclusion criteria.

The degree of recruitment of cases was likely to vary within the catchment area of the hospital since there are other smaller health care units in the most distant parts of the area. The study base was therefore defined by the postal zip codes of cases at the time of diagnosis for cases and at the year of enrolment for referents. When relevant, the material was analysed separately for men and women stratified into three age groups: 25–40, 41–55, and 56–75 years of age at the time of diagnosis for cases and at the year of enrolment for referents. When relevant, the material was also stratified into three smoking categories (non-smokers, past or present occasional smokers, and past or present regular smokers), and for some analyses stratification was also made for occupation, marital status, and socioeconomic status.

The results are presented for assessments of a priori hypotheses based on earlier findings from the literature. New associations are presented when the number of exposed subjects was at least 10 and the risk estimate was \(>1\) or \(<0.5\), or otherwise significantly different from unity. Analyses were performed on the association between the start of exposure and the year of diagnosis according to the ARA for cases, and the year of dummy date of onset for referents. When considered relevant, analyses were also performed to examine the association between start of exposure and year of onset of symptoms for cases. Exposures occurring after these dates were disregarded. To be regarded as exposed, subjects were required to have a minimum duration of exposure of 6 months.
Assuming varying latency periods for different exposures, different latency requirements were tested, when relevant, for each determinant. Cases who were rheumatoid factor (RF) seropositive according to the medical records were analysed separately.

All determinants identified in the stratified analyses presented in this paper or in the separate publication on occupational exposures as having risk estimates of $\geq 1.5$ or $\leq 0.5$ when the number of exposed subjects was at least 10, or when otherwise significantly different from unity, were included in a bivariate correlation matrix. All variables found to have a Pearson correlation coefficient of at least 0.500 were then included in the logistic regression analyses using the computer program SPSS (SPSS Inc, Chicago, IL, USA) to evaluate possible confounding. Men and women were analysed separately.

Unless otherwise stated, the risk estimates presented in the text result from analyses of the association between the start of exposure and the time of ARA diagnosis, without latency requirement, with both seropositive and seronegative cases included.

### Results

Two hundred and eighty one cases and 507 referents participated in the study, resulting in response rates of 67% and 59%, respectively. The mean age was 62 years for the cases and 58 years for the referents, and 64% and 51%, respectively, were women. Seventy nine per cent of the cases were seropositive. The mean duration of the disease in the cases at the time of entry into the study was 8 years, as was the mean time span between the dummy date of onset and entry into the study for referents. For cases the mean interval between year of onset of symptoms and year of diagnosis was less than four years.

The response rate was low and therefore the possible influence of non-response bias was evaluated. These results are presented in detail in the study on occupational determinants of importance for RA. In summary, the comparison revealed that non-responding women were older than the women who responded, and that all non-responders were more likely to be single and to earn less than the corresponding group of responders.

Men who were current smokers had a significantly increased occurrence of RA (exposed cases/referents 40/62, odds ratio (OR) 2.2, 95% confidence interval (CI) 1.1 to 4.2, with adjustment for age and socioeconomic status). Pack years of smoking were calculated by multiplying the mean number of packs per day by the total number of years of smoking. Those with no previous use of any form of tobacco were regarded as the reference group.

The results are presented in table 1. In men an increase in risk was found with increasing number of pack years. Slightly increased risks were at first seen for non-smoking men passively exposed to smoking fumes and for men reporting previous use of tobacco for buccal application (Swedish snuff), but the risks did not remain when adjustment was made for socioeconomic status.

A non-significant increased risk of RA was seen in both men and women who consumed at least 750 ml of alcohol per drinking session at the age of 25 compared with total abstainers. With adjustment also for smoking and socioeconomic status, the ORs decreased towards unity (data not shown).

When men and women were analysed together with adjustment for age and sex, atopic allergy was less common amongst cases than among referents (exposed cases/referents 32/81, OR 0.6, 95% CI 0.4 to 1.0) and this difference was almost significant. The results were similar after adjustment for smoking habits.

When the cause of the allergy was examined, somewhat decreased ORs were seen for allergic reactions to pollen (exposed cases/referents 13/39, OR 0.6, 95% CI 0.3 to 1.2) and to house dust (exposed cases/referents 3/8, OR 0.5, 95% CI 0.1 to 2.0). The results for men and women are shown in tables 2 and 3.

Results regarding other comorbidity, previous infections and medication, as well as results concerning educational level, residential exposure, some other external factors and psychosocial stress are also shown in tables 2 and 3. Only one of the women who reported use of insulin had previously been treated with corticosteroids. Vaccinations did not influence the risk of RA (data not shown). Most of the women who reported a joint injury at least 20 years before the diagnosis of RA did not have their injury before the age of 20. Previous operations...

The use of prevalent cases of RA from the University Hospital in Linköping may have resulted in a selection bias. It is possible that those affected by more severe disease had died before the time of inclusion in the study, while those with less severe disease may have been referred to other health care units. Assuming an association between the analysed factors and disease severity, it is possible that those who had died represent cases exposed to risk factors and unexposed to preventive factors, while the opposite could be assumed for the less severe cases. However, even if an association between certain factors and disease severity is assumed, a possible counterbalancing loss of extreme cases can be expected to minimise the selection bias.

Several kinds of exposures, which probably have different mechanisms of action, have been

and other kinds of trauma were not associated with RA (data not shown). No increase in risk was seen from exposure to pets (data not shown). Apart from the non-significant increase in the risk for RA in women exposed to

sols, no associations between RA and leisure time exposures to chemicals were found (data not shown).

The results on reproductive factors are shown in table 4. “Normal” age of menarche and menopause was defined from the age distributions seen in the female referents, and those with onset of menarche at age 13–15 and of menopause at age 48–53 were considered as the reference group. When the onset of menopause was studied, those with a history of gynaecological operations (12 cases and 20 referents) were excluded from the analyses. In consideration of the length of the fertile period, those with a fertile period of 34–40 years were regarded as the reference group. There was no difference between cases and referents with regard to interrupted pregnancies (data not shown).

The logistic regression analyses did not produce any major changes in risk estimates to indicate confounding in men or women. Apart from some occupational exposures, the analyses included exposure to farm animals and private wells for men, and oral contraceptive use and some psychosocial factors for women.

Discussion

The response rate was lower than expected, and analyses were therefore made to evaluate the possible presence of a non-response bias. When age, socioeconomic status, and income were studied, there were no indications of a systematic non-response bias concerning socioeconomic factors since the observed differences between responders and non-responders seemed to be of similar magnitude in both cases and referents.

Subjects were unaware of the specific aim of the study and of their case-referent status to avoid any possible recall bias and most of the hypotheses tested are unknown to the public. When age, socioeconomic status, and income were studied, there were no indications of a systematic non-response bias concerning socioeconomic factors since the observed differences between responders and non-responders seemed to be of similar magnitude in both cases and referents.

The use of prevalent cases of RA from the University Hospital in Linköping may have resulted in a selection bias. It is possible that those affected by more severe disease had died before the time of inclusion in the study, while those with less severe disease may have been referred to other health care units. Assuming an association between the analysed factors and disease severity, it is possible that those who had died represent cases exposed to risk factors and unexposed to preventive factors, while the opposite could be assumed for the less severe cases. However, even if an association between certain factors and disease severity is assumed, a possible counterbalancing loss of extreme cases can be expected to minimise the selection bias.

Several kinds of exposures, which probably have different mechanisms of action, have been
studied, and it is reasonable to assume different latency periods for these. Varying latency requirements have therefore been tested and used when relevant.

There was an increased risk for RA in both current and previous smokers, and in men there was a dose-response relationship which further strengthens the credibility of a true cause-effect relationship. These results are in agreement with previous findings. The tendency for higher ORs in seropositive cases is also in agreement with previous findings of an association between smoking and RA severity. Smoking may also cause an increased production of RF in non-rheumatic subjects and the RF concentration in patients with RA has been shown to be linearly related to the number of years of smoking. Furthermore, the association between smoking and RA, especially seropositive RA, seems to be stronger in men than in women.

Education has been regarded as a socioeconomic marker and a low educational level has previously been found to be associated with an increase in severity of RA. However, in a recent study no association was seen between RA and a low educational level. In the present study an inverse relationship between educational level and RA prevailed after adjustments for smoking habits and occupation. It is possible that a higher educational level is associated with a healthier lifestyle or a different pattern of healthcare use.

A recent study has shown that coffee consumption is associated with both RF seropositivity and development of RA. This is interesting because the amount of coffee consumed is likely to vary with other lifestyle factors previously found to be associated with RA such as smoking. However, questions concerning coffee consumption were not included in the present study.

Previous studies of the coexistence of atopic manifestations in patients with RA have shown an inverse relationship between the two conditions, supporting the theory of a functional dichotomy between Th1 and Th2 type responses. Assuming a lifelong commitment to either Th1 or Th2 type responses, a history of allergic manifestations in cases and referents was compared. The results from the present study support an inverse relationship between RA and atopic allergy, while the results concerning the presence of asthma and eczema were divergent between the sexes. It is possible that subjects have reported other than atopic conditions and Th1 mediated contact dermatitis might have been reported as atopic eczema. The question concerning atopic allergy is probably more reliable and is supported by the decreased risk of allergic reactions to pollen and house dust.

An association between Th1 dominated conditions is supported by the relationship between RA and insulin treatment in women as diabetes mellitus type 1 is considered to be a Th1 condition. Autoimmune thyroiditis is also regarded as a Th1 condition and has previously been found to be associated with RA. However, those reporting thyroid conditions in this study may also have had other thyroid diseases.

Various infections have been suggested to contribute to the development of RA, and the association with antibodies in men seen in this study may be regarded as an indication of previous bacterial diseases. In women there was also an unexpected negative relationship between RA and rubella, previously considered to be a possible risk factor for RA.

The increased risks associated with the use of a private well and problems with mould indoors are new findings. Private wells are found in the countryside in Sweden, and the risk might be conveyed by contamination of chemicals used in nearby cultivations. Wells can also contain various organic degradation products, minerals, and bacteria.

The increased risk of RA associated with customer exposure to hair dyes and/or bleach prevailed after adjustment for work as a hairdresser. Hairdressers have previously been found to have an increased risk for RA and for lymphoma, a condition associated with RA and possibly also associated with customer use of hair dyes.

The significantly decreased risk seen in women who have ever breast fed a child is not in accordance with the suggested association between RA and hyperprolactinaemia. However, such an inverse relationship has also been reported previously. Although previous studies have not associated treatment with non-contraceptive sex hormones with any major change in risk of RA, our study indicates a possible beneficial effect from their use.

In conclusion, the findings support the hypothesis of a functional dichotomy between RA and atopy, which is characterised as a Th2 dominated disease, while there is a clinical correlation between RA and other Th1 dominated conditions such as diabetes mellitus. Most of the results relating to the role of reproductive factors and hormonal treatment are in agreement with existing theories on the influence of hormonal factors on the development of RA. Furthermore, the negative impact of lifestyle factors such as smoking is confirmed while higher education seems to have a protective effect. Most of the results on external factors such as physical and psychological trauma and residential exposures are hypothetical as there are no obvious explanations for these findings. It is likely that the risk factors and beneficial factors reported in this study act together with other aetiological or protective factors to facilitate or to prevent the end point of RA. Further studies are warranted to confirm this.
MATTERS ARISING

Heavy cigarette smoking and RA

Hutchinson et al concluded that prolonged heavy cigarette smoking, but not smoking itself, is strongly associated with rheumatoid arthritis (RA), particularly in patients without a positive family history.1 The authors proposed that increased rheumatoid factor (RF) production resulting from heavy smoking exposures explains, in part, the relation of increasing cumulative pack years smoked and the greater association with RA.1

No data were presented in that study on the extent of smoking and RF positivity or its titres. The proposal1 would be strengthened if heavy smoking were associated with RF either when clinical disease began or when patients were studied at hospital rheumatology clinics. Others have proposed that tobacco smoke exposure triggers RF production, thereby contributing to the onset of RA.4 However, no significant association was seen between current smoking and IgM RF positivity in the earlier multicase family study1 either among 41 patients with RA or their non-rheumatoid relatives—168 blood and 36 non-blood relatives.4

Although heavy cigarette smoking may be associated with RF during clinical disease, it is still relevant to determine whether it is associated with RA, either in the presence or absence of RF positivity. A further question remains as to the sequence of occurrences. Does heavy smoking first induce RF production, which later contributes to RA5 or alternatively, might RA be induced first and RF produced later? Prospective, rather than cross sectional, studies are needed to answer these questions. Prospective data suggest that reported smoking of 30 or more cigarettes daily (CS 30+/day) predisposes to RA risk independently from RF positivity or positive family history.6

These complex relationships were investigated in a case-control study nested within a community-based cohort (n=21 061 adults) enrolled in 1974. For each of the 18 male and 36 female unrelated incident patients who satisfied American College of Rheumatology criteria for RA, identified in 1994, four controls from the entry cohort were matched for age, sex, and race (all white subjects).1

Table 1 shows the number of patients before they developed RA and their respective controls who reported heavy cigarette smoking (CS 30+/day) at baseline. Heavy smoking was not associated with pre-RA RF+ status, but was associated significantly (p=0.001) with patients who were RF− at baseline. The highest observed odds ratio (OR) was in 15 sets in which the patient was RF− at baseline and continued to be RF− after active disease developed [OR 21.5, 95% CI 1.9 to 222.5, p=0.005]. The ORs were similar for sets in which the patients had positive or negative FDR status, but was significant (p=0.012) only in the larger FDR− subset (table 1).

The hypothesis that cigarette smoking contributes to RA partly by RF production1 is attractive. However, critical substantiation in prospective and cross sectional studies is currently lacking. Available prospective data (table 1)1 suggest that alternative mechanisms may be more likely. For example, long term cigarette smoking causes general vascular endothelial damage, and smoking is significantly associated with vasculitis in active RA.1 Heavy smoking was proposed to contribute to RA risk through its endothelial and microvascular effects, perhaps through nitric oxide pathways,4 rather than by RF production primarily.4

Whether or not heavy smoking differentially associates with RA depending upon family history of disease is as complex as the dilemmas of RF contributions to onset (table 1). Our patients had a significantly (p=0.001) younger mean age at clinical onset (45.6 years) than their counterparts (57.1 years). Might such earlier onset of RA among patients with a positive family history, as also noted by Silman et al, have influenced their behaviour to lower cumulative exposures to cigarette smoking compared with their counterparts?1

Table 1 Numbers of pre-RA cases and matched controls reporting heavy cigarette smoking (CS 30+/day) at baseline by relevant categories and odds ratios (ORs) with 95% confidence intervals (95% CIs) for developing ACR+ rheumatoid arthritis

*FDR+ is a positive history of RA in a first degree relative as determined for patients in 1997, and reported was seen between current smoking and IgM RF during clinical disease, it was not associated with rheumatoid arthritis (RA), particularly in patients without a family history of RA. Ann Rheum Dis 2001;60:223-7.

†Conversion of RF− at baseline to RF+ after clinical onset of RA.

‡Course of RA over 3–20 (median 11) years of clinical disease was determined by the patients’ rheumatologist according to predefined criteria.

§No association of CS 30+/day with pre-RA RF+ (p=0.99).

Authors’ reply

We read the letter of Masî et al with interest and are pleased to have an opportunity to discuss the questions they have raised. Our study group was derived from an area of northwest England made up principally of people in a lower socioeconomic class, in contrast with other UK studies. Although we did not record the presence of rheumatoid factor (RF) in our patients for the purpose of this study, seropositivity in our RA patient group was high, approximately 80–90%. This is comparable with Glasgow, an area in Scotland with a similarly high level of social deprivation, where 96% of randomly selected patients with RA were found to be seropositive.2 We therefore decided to compare the smoking history of familial and sporadic patients with RA rather than compare seropositive and seronegative patients.

Published reports almost uniformly suggest that cigarette smoking is associated with seropositive rather than seronegative RA. Cigarette smoking is associated with the development of seropositivity in healthy subjects1 and, furthermore, there is a dose related phenomenon for the development of seropositive RA.3 It has also been established that the development of seropositive RA is greatly increased in healthy subjects who are persistently seropositive.4 Wolfe noted a significant trend in patients with RA of...
increasing RF titre with pack years smoked. Yet although the development of rheumatoid joint erosions, nodules, and disability was significantly increased by cigarette smoking, he found that this was independent of RF production. We suspect that cigarette smoking and RF are strongly interlinked, but other mechanisms, as suggested by Mas, may also be at work. For example, cigarette smoke contains numerous oxidising agents that can inactivate α-proteinase inhibitor (α-PI), the natural inhibitor of neutrophil elastase (NE), a serine protease that can degrade articular cartilage. Cigarette smoke can also prime neutrophils to degranulate and discharge NE, activate macrophages to produce matrix metalloproteinases, up regulate production of interleukin 1β and interleukin 8 and down regulate interleukin 1 receptor antagonist, and interleukin 10. Furthermore, cigarette smoking induces disease processes in a specific dose dependent fashion (independent of current smoking status), such as pulmonary emphysema, in which there is increased neutrophil priming, increased oxidised α-PI and α-PI-NE complexes (inductive of increased NE activity). Therefore a heavy smoker may have an otherwise benign short lived inflammatory arthritis modified by the mechanisms outlined above and develop RA. Whether RA increases or decreases cigarette consumption remains uncertain. Our controls had a pack year total that was equal at entry to the study and not at the time of their disease onset. We are, however, unaware of any data to suggest that RA increases cigarette consumption. Indeed, a study by Harrison et al. has observed that 18% of all smokers with polyarthritides stopped smoking within three years of disease onset as opposed to <1% of non-smoking patients who started smoking during this period.

Other important questions remain unanswered. For example, does increased cumulative cigarette consumption increase RA susceptibility independently of RP production? Does smoking affect by Masi et al. consider cigarette consumption at one time point? If so, do these subjects have an increased prevalence of circulating levels of α-PI-NE complexes, high levels of oxidised and inactivated α-PI-PE complexes, and therefore pulmonary emphysema? We welcome the heightened interest in the relationship between smoking and RA and look forward to the establishment of new studies designed to answer some of the interesting questions raised by recent studies.

Rheumatoid arthritis associated with ulcerative colitis

I was interested to read the letter on “Rheumatoid arthritis associated with ulcerative colitis” by Boyer et al published recently in the Annals, and would like to make the following comments. Studies in patients with established Crohn’s disease (CD) have generally supported the predominance of Th1 responses. In ulcerative colitis, although enhanced humoral immunity has been described, evidence for classical Th2 predominance remains to be demonstrated. On the other hand, it has been shown that interleukin 15 is overexpressed in the inflamed mucosa of patients with inflammatory bowel disease at the level of macrophages. Similar findings have been reported in patients with rheumatoid arthritis (RA).

As shown in this case, it is sometimes quite difficult to distinguish by clinical manifestations alone between two diseases which start almost at the same time. However, the presence of a positive rheumatoid factor and DR1 genotype are arguments for RA. The existence of polymorphisms affecting other genes may take place in such type of arthritis. Results obtained with anti-tumour necrosis factor monoclonal antibodies to prevent mucosal inflammation in CD, suggest that such an approach may also be of interest in this unusual situation.

We thank Dr Mosquera-Martinez for his letter and are happy that our report has stimulated active discussion and suggestions. Indeed, control of disease was difficult even when combining methotrexate 15 mg/week IM, salazopyrine 3 g/day, and prednisone 10 mg/day. The patient still had active arthritis affecting wrists and hands with an erythrocyte sedimentation rate (ESR) of 47 mm/1st h. Furthermore, she also had active colitis, and current treatment prevented surgery for colon anastomosis. Accordingly, infliximab was started following the now classical rheumatoid arthritis protocol. Seven months later, steroids could be stopped. Surgery for permanent colon anastomosis could then be performed with success and with no healing delays. When last seen in July 2001, she showed major improvement, with no pain at night and no morning stiffness. She had gained weight and had no sign of active colitis. The ESR was 26 mm/1st h and C reactive protein <4 mg/l. Such follow up extends the concept of common mechanisms between rheumatoid arthritis and ulcerative colitis. Both diseases appear to depend, at least in part, on the contribution of tumour necrosis factor α.

Intramuscular methotrexate in inflammatory rheumatic disease

We read with great interest the recent letter entitled "Parenteral methotrexate worth trying?" by Osman and Mulherin. There has been an increased use of intramuscular methotrexate (IM-MTX) in our department in the past two years, leading to an increased workload in the nurse-led monitoring clinics and in the cost. This has prompted us to review the clinical utility of switching patients to IM-MTX. In addition, we have recorded patients’ experiences, focusing chiefly on patient satisfaction, with this treatment.

Medical case notes of 31 patients who had started treatment with IM-MTX, identified from our database, were examined. The clinical diagnosis, previous drug treatment, reason for changing to IM-MTX, efficacy, and side effects were noted. In addition, the patients were asked to complete a questionnaire, looking at patient satisfaction and preferred venue for injections (monitoring clinic or local doctor’s surgery/home).

Our cohort had comprised of 24 patients with rheumatoid arthritis, four with spondoretovoidarthropathy, two with systemic lupus erythematosus and one with undifferentiated connective tissue disease. Most patients had been receiving a previous disease modifying antirheumatic drug (DMARD), including 24 patients taking oral MTX. Reasons for changing to IM-MTX treatment were as follows: side effects 11 patients, loss of efficacy in 12, and poor oral compliance in 8. The median starting and maintenance doses were 10 mg weekly (range 5–17.5) and 15 mg weekly (range 10–17.5), respectively. During the study, five patients discontinued IM-MTX: two because of side effects, one developed multiple nodulosis, one did not attend for follow up, and one died from an unrelated cause. Median duration of treatment in the remaining 26 patients was 10 months (range 1–20). Significant improvement in disease activity, as measured by erythrocyte sedimentation rate and C reactive protein, was seen after three months (p<0.01), with improvement maintained after nine months (p<0.01) of IM-MTX treatment. Twenty four of the 26 current patients who had completed the questionnaire on a satisfaction scale of 1–5, the average rating was 4.2; indicating that patients were either very or extremely satisfied with their IM-MTX treatment. Fourteen patients preferred their injections in the monitoring clinic, five patients preferred their local doctor’s surgery, and five patients expressed no preference. Only three patients stated that weekly clinic visits were inconvenient.

In conclusion, we found that IM-MTX was effective and well tolerated. In addition, our observations further support the switch to parenteral MTX in those patients previously intolerant or who have failed to respond to oral MTX. Surprisingly, most patients preferred to have their injections in the monitoring clinic. The reason for this is not clear. Possibly, the patients felt more confident if cytotoxic drugs were given by a trained healthcare professional, although a previous study by Arthur et al has found that self injection of DMARDs is safe, convenient, and time and cost saving to the patient. We are currently comparing the administration of parenteral MTX in the monitoring clinic with self administration in the community. Regardless of the outcome, the role of parenteral MTX in rheumatic diseases is likely to expand and the cost and resource implications of continuing with this treatment need to be discussed.

Author’s reply

It is gratifying that Drs Burbage, Gupta, and Lim have also demonstrated efficacy and high levels of patient satisfaction associated with parenteral methotrexate in their study. There remains a surprising dearth of reported information about this useful and widely prescribed development in rheumatology practice. Because of the burgeoning number of patients being treated in this way, it is creating increasing logistical difficulties. It represents an unlicensed use of this drug, which can cause anxiety among less experienced practitioners. Issues related to the appropriate disposal of the residual cytotoxic waste have also caused considerable difficulties. Although weekly oral methotrexate, prescribed and monitored within primary care, is an extremely cheap and effective treatment for rheumatoid arthritis, this is certainly not the case for parenteral methotrexate if it is necessary for it to be prescribed and administered in a costly secondary care setting. As primary care buckles under increasing demands on its resources, cost and logistical issues, rather than issues of efficacy, may curtail the desired role of parenteral methotrexate in current and future rheumatology practice.

Epidemiology of vasculitis in Europe

We recently compared the annual incidence of primary systemic vasculitis (PSV) in two different regions of Europe (Norwich, UK (latitude 52°N) and Lugo, Spain (latitude 43°N)). Wegener’s granulomatosis (WG) was more common in Norwich (10.6/million) than in Spain (4.4/million), though the overall incidence of PSV was similar. This supports the idea that environmental factors may be important in the aetiopathogenesis of PSV. To extend our observations we have now studied the incidence of PSV in northern Europe (Tromsø, Norway (latitude 70°N)). The same methodology was used as in the previous study. All new patients presenting with PSV between 1 January 1988 and 31 December 1998 were identified in the three centres. WG, Churg-Strauss syndrome (CSS), and polyarteritis nodosa (PAN) were classified by the American College of Rheumatology (1990) criteria, and microscopic polyangiitis (MPA) and classical PAN by the Chapel Hill consensus definition. Incidence figures were calculated using the Poisson distribution for the observed number of cases.

Table 1 shows the results obtained. The overall incidence and pattern of vasculitis was similar in the three regions, but there were some differences. MPA was less common in Tromsø than in the other two regions, and there was a trend for WG to be more common in the north. CSS was more common in Norwich than in the other two regions. In all areas and all disease categories the incidence was greater in men than women and showed a peak incidence at age 65–74. Overall, WG is the most common type of PSV and classical PAN the rarest.

These results support the notion suggested by doctors interested in vasculitis that there are geographical differences in the incidence of WG, MPA, and CSS, and, in particular, there is an inverse relation between the incidence of WG and MPA. In clinical practice MPA and WG can be difficult to distinguish. Possibly, despite our best attempts to harmonise the application of classification criteria/definitions, there were still differences in approach. The reason for the apparent excess of CSS in Norwich is unclear.

but might reflect local environmental factors. The aetopathogenesis of PSV is unknown, but both genetic and environmental factors are likely to be important. The clinically observed differences between MPA and WG may reflect interaction of varying trigger factors on a heterogeneous genetic background. It should therefore not be assumed that the same triggers operate in all regions of Europe.

Antibodies to U3 snRNP in Localised Scleroderma

Localised scleroderma (LScl) is a connective tissue disorder usually limited to the skin and subcutaneous tissue, but it sometimes affects the muscle beneath the cutaneous lesions. The absence of Raynaud’s phenomenon, acrosclerosis, and internal organ involvement differentiates LScl from systemic sclerosis (SSc). 1 LScl has been reported to be accompanied by a variety of abnormal immune reactions, such as the presence of antinuclear antibody, rheumatoid factor, anti-single-stranded DNA antibody (anti-ssDNA), and antihistone antibody. 2

In our laboratory, an indirect immunofluorescence study showed nuclear staining in the serum samples of some patients with LScl. Although autoantibodies to nuclear antigens have been well described in patients with SSc, 3 some antibodies have not been determined in patients with LScl, and the incidence of anti-U3 snRNP antibodies has not been described previously. In this study we investigated the prevalence of anti-U3 snRNP antibodies in patients with LScl using RNA immunoprecipitation, and examined the clinical and laboratory features of patients with LScl. In addition, we examined the serum samples of patients with SSc and control subjects matched for age and sex with the patients with LScl.

We found anti-U3 snRNP antibodies in 2/70 (3%) serum samples from the patients with LScl (fig 1). One of the 28 patients (4%) with linear scleroderma and one of the 20 patients (5%) with morphea had anti-U3 snRNP antibodies (table 1). This prevalence was smaller than that in patients with SSc, 4 but there was no significant difference. RNA immunoprecipitation using silver staining of the RNA is not as sensitive as other methods—for example, probing with a labelled U3 snRNP probe. Possibly, some anti-U3 snRNP positive serum samples might have been missed. The three patients with SSc and with anti-U3 snRNP antibodies were diagnosed as having diffuse cutaneous SSc, and they tended to be older and have disease of longer duration than patients with LScl; the difference was not significant. In this study the titres of antinuclear antibodies in the two patients with LScl with anti-U3 snRNP antibodies were 1/320 and 1/640, respectively. The titres of this antibody did not change in a follow up study. A previous study reported that 43/46 patients with SSc and anti-U3 snRNP antibodies produced bright nucleolar staining with titres >1/640. 10 Taken together, the titres of antinuclear antibodies in patients with LScl were as high as those in SSc. Patients with LScl and with anti-U3 snRNP antibodies did not have sclerodactyly or nailfold bleeding. Raynaud’s phenomenon did not occur at any time in the course of their disease. These results suggest that anti-U3 snRNP antibodies occur in patients with LScl as well as in those with SSc.

The patients with LScl and anti-U3 snRNP antibodies tended to be younger, have shorter disease duration, have fewer sclerotic lesions, and have fewer affected areas than those without, but there was no significant difference. We could not find any correlations with clinical manifestations, probably because of the small number of patients. In earlier investigations of systemic sclerosis, anti-U3 snRNP antibodies did not seem to have any distinctive clinical and laboratory correlation. A large group of patients with SSc was assembled and the clinical features of the patients with anti-U3 snRNP antibodies investigated; various clinical, laboratory, and autoantibody data were reported. 4 A large group of patients with LScl might similarly disclose clinical associations of patients with LScl with anti-U3 snRNP antibodies.

Previous studies have shown that anti-U3 snRNP antibodies rarely coexist with other autoantibodies. 11 Okano et al reported that each distinctive serum antibody is associated with its own unique combination of clinical features. 12 In our study anti-U3 snRNP antibodies were found in patients with LScl by RNA immunoprecipitation. LScl may be a heterogeneous condition with diverse autoantibodies, and these antibodies may have a mutually exclusive status.

In conclusion, we showed for the first time that anti-U3 snRNP antibodies are found in patients with LScl by RNA immunoprecipitation. We found no correlations between clinical and laboratory manifestations in the present study. Our study suggests that the prevalence of anti-U3 snRNP antibodies is one of the serological abnormalities in LScl. A study of more patients may assist in showing a distinctive association between anti-U3 snRNP antibodies and the clinical and laboratory features of patients with LScl.

Telomerase activity in peripheral blood mononuclear cells from patients with SLE

Telomerase is a reverse transcriptase that adds the telomeric sequence to the terminal of chromosomes, prevents shortening of telomere, and maintains the complete telomeric structure. It has been recently reported that an increase in telomerase activity is associated with the activation of lymphocytes, and, in general, much attention has been paid to the role of telomerase in immunopathology. Katayama et al reported the telomerase activity in patients with systemic lupus erythematosus (SLE). They analysed 17 patients with SLE, and the telomerase activity in peripheral mononuclear cells was increased to 64.7%. Thus, in this study, we divided patients with SLE into treated and untreated groups, and measured the telomerase activity of peripheral mononuclear cells.

Thirteen patients with SLE (1 man, 12 women) with a mean (SD) age of 30.7 (6.5) years (range 19–61) were enrolled in this study. All patients fulfilled the 1997 revised American Rheumatism Association criteria. As a control group, 10 normal volunteers, six women aged 19–41 and four men aged 30–37, were also included in the study. After informed consent had been obtained, 10 ml of peripheral blood was taken and heparinised. The mononuclear cell fraction was isolated from 10 ml of heparinised peripheral blood by Ficoll-Paque (Sigma Inc, St Louis, USA) density gradient centrifugation. A sample of 1,0×10^6 mononuclear cells was analysed by the TRAP assay method. The TRAP assay was performed with a TRAPeze telomerase detection kit produced by the InterGene Company (Purchase, NY, USA). The level of telomerase activity was expressed by a ratio of the entire TRAP ladders to an internal control band.

Table 1 shows the telomerase activity level data and clinical data used for determining the SLE Disease Activity Index (SLEDAI). Significant differences (p=0.006) were detected in the telomerase activity level between the control group, untreated SLE group, and treated SLE group by the Intergen Company (Purchase, NY, USA). The level of telomerase activity was analysed by the TRAPeze telomerase detection kit produced by the InterGene Company (Purchase, NY, USA). The level of telomerase activity was expressed by a ratio of the entire TRAP ladders to an internal control band.

Treatment of ankylosing spondylitis with infliximab

In January 2000 a 35 year old man presented with severe ankylosing spondylitis (AS), diagnosed in 1981. The Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) was 6.0, the Bath Ankylosing Spondylitis Functional Index (BASFI) was 3.0, and on a 1–10 visual analogue scale (VAS) for pain in the previous two months he had a score of 6.

The patient denied any loss of extension at the end of one year's treatment. Except for the mild upper respiratory tract infection, which abated after two weeks without specific treatment, there were no adverse events. Two mobility variables (cervical rotation and tragus-wall distance) had improved at the end of one year's treatment.

We started treatment with infliximab, a monoclonal antibody (IgG1) directed against tumour necrosis factor α (TNF-α), at a dose of 5 mg/kg body weight. Intravenous infusions were given in weeks 0, 2, 6, and then continued at weekly intervals for one year without any additional disease modifying drug.

Pain improved within 24 hours of the first infusion. Within six weeks the patient required no ibuprofen and CRP, ESR, BASDAI, BASFI, and VAS improved dramatically (fig 2). With the exception of CRP and ESR, all variables remain normal up to now. CRP and ESR increased mildly at week 12 owing to a mild upper respiratory tract infection. There were no other adverse events. Two mobility variables (cervical rotation and tragus-wall distance) had improved at the end of one year's treatment. Except for the mild upper respiratory tract infection, which abated after two weeks without specific treatment, there were no adverse events.

This case report documents the first long term application of infliximab in a patient with AS. Two previous studies reported effective treatment of a total of 22 patients with AS with three infusions of infliximab at a dose of 5 mg/kg body weight.

The pharmacological basis for TNF-α inhibitory treatment in AS is the detection of TNF-α-mRNA and TNF-α protein in biopsy specimens of ileosacral joints of patients with active AS. In rheumatoid arthritis (RA) and Crohn’s disease (CD), several TNF-α inhibitors seem to be successful in significantly reducing inflammatory activity.

Theoretically, up regulation of the TNF-α receptors and subsequent tachyphylaxis might be expected upon constant blockade of the agonist. This has not been noted in studies on infliximab, etanercept, and D2E7 in RA, CD, and psoriatic arthritis (PA) during long term treatment, even when constant therapeutic plasma levels are maintained.

In summary, we present the case of a patient with AS effectively and safely treated with infliximab over a period of more than one year. This indicates that treatment of AS with TNF-α inhibiting substances may have equal long term safety and long term benefits on peripheral and spinal joint function as does treatment of RA, CD, and PA. Randomised controlled double blind studies are needed to investigate this in further detail.
Retrocalcaneal bursitis in polymyalgia rheumatica

Polymyalgia rheumatica (PMR) is a relatively common disease of the elderly affecting the synovial membrane. Recent studies have emphasised the prominent involvement of the extra-articular synovial structures in both proximal and distal processes of the disease.

In the distal part of the arms and feet, PMR involves synovial structures responsible for carpal tunnel syndrome. The ankle joint and its entheses also show peculiar features, with evidence of Achilles tendon involvement. In particular, the typical gait and abnormal stance in PMR can be attributed to Achilles tendon involvement.

The presence of retrocalcaneal bursitis in PMR has been reported in several studies. The retrocalcaneal bursa is a synovial structure located just beneath the calcaneal tendon and is responsible for cushioning the tendon and preventing friction during weight-bearing activities.

In conclusion, the presence of retrocalcaneal bursitis in PMR further supports the idea of a systemic inflammatory process involving extra-articular structures. This highlights the importance of considering the distal manifestations of PMR in the management and treatment of the disease.

Figure 1: Sagittal T1 (A) and axial T2 (B) weighted images of the left Achilles tendon showing a fluid collection (arrows) together with normal Achilles tendon and enthesis.

CORRECTION

Comorbidity and lifestyle, reproductive factors, and environmental exposures associated with rheumatoid arthritis

The authors regret that an error is present in the fourth paragraph of the “Results” section. The first sentence should read: “A non-significant increased risk of RA was seen in both men and women who consumed at least 75 ml of alcohol per drinking session at the age of 25 compared with total abstainers” and not “750 ml” as stated.

(Note: Corrections printed in the journal also appear on the Annals web page (www.annrheumdis.com) and are linked to the original publication.)

EULAR training bursaries

Up to 10 scholarships for clinical or laboratory work (3–6 months) in a foreign unit will be made available for applicants from countries where there is a clear educational need. The value of each bursary is 7000 euros. Candidates should be under 35 years of age and the grant will not be made if the applicant is already abroad in training. A curriculum vitae, a statement of qualification, a project outline, and a written confirmation from the host hospital that training is possible must be received at the EULAR Secretariat no later than 28 February 2002.

EULAR prize

The prize, to the value of 30,000 euros, is awarded by EULAR for an outstanding contribution in the field of rheumatology in recent years. The competition is open to both scientists and clinicians working in the field of rheumatology. The prize will be awarded for the work of a group and not to an individual person. The documents submitted in support of an entry may take the form of an essay or a description of the project. The prize will not be awarded for a publication or an abstract. The essay with the CV of the head of the group and a publication list must be received at the EULAR Secretariat in Zurich no later than 28 February 2002.

EULAR young investigator awards

Three awards for a scientific (clinical or basic) research project of 30,000 euros each, will be made available for laboratory/research work in the field of rheumatology. Candidates must submit a project outline, a CV, and expense budget and should be under 35 years of age. Entries for the Young Investigator Awards must be received at the EULAR Secretariat in Zurich no later than 28 February 2002.

AMGEN/EULAR young investigator award

AMGEN (Europe) will make an award of 30,000 euros for a scientific (clinical or basic) research project in the area of rheumatoid arthritis. The prize money is intended to support laboratory/research work. Candidates must submit a project outline, a CV, and expense budget and should be under 35 years of age. Entries for the award must be received at the EULAR Secretariat in Zurich no later than 28 February 2002.

Endowment of the awards

The EULAR prize, the EULAR young investigator awards, and the AMGEN/EULAR young investigator award will be endowed at the opening ceremony of the Annual European Congress of Rheumatology to be held in Stockholm, Sweden, on 12 June 2002.
