MATTERS ARISING

Management of knee osteoarthritis

I read with great interest Dr Jawad’s letter and the authors’ reply about the EULAR recommendations for the management of knee osteoarthritis (OA).

Although most points of criticism were answered by M. Dougados and M. Doherty it seems to me that treatment of knee OA with symptomatic slow acting drugs in osteoarthritis (SYSADOA) and cox-2 (COX-2) inhibitors needs to be discussed in a different way in the light of recent publications.

With respect to SYSADOA, the statement that these substances may modify structure has been strengthened by the publication of Reginster et al., in which glucosamine sulphate (GS) treatment was proved to exert a significant decrease in joint space narrowing compared with placebo during a three year period, indicating the disease modifying effect of GS for the first time.

Moreover, symptomatic efficacy was shown using the WOMAC index as an outcome measure.

As a member of the ESCISIT task force I feel free to discuss some of the issues raised by Dr Jawad and to give further arguments for the accuracy of the recommendations developed by the group of European experts.

As a member of the members dealing with possible disease modifying properties of hyaluronic acid are well known, and trials investigating the same effect in chondroitin sulphate (CS) are currently underway. Two meta-analyses as well as controlled trials have provided evidence for the symptomatic efficacy of GS and CS and proved their overall excellent tolerability, when compared with treatment with non-steroidal anti-inflammatory drugs (NSAIDs).

With respect to COX-2 inhibitors, to my knowledge no publication exists to show that COX-2 inhibitors, such as Rofecoxib and Celecoxib, are more efficacious than classical NSAIDs. On the other hand, all the studies indicate better gastrointestinal tolerability of both these new compounds, but some severe gastrointestinal toxicity and dyspepsia, comparable with classical NSAIDs, has been noticed. When dyspepsia occurs it is not possible to predict erosions or an ulcer and, therefore, endoscopy has to be performed if epigastralgia occurs. This reduces the potential for cost saving with the new compounds and is inconvenient for patients. Thus the advantages of COX-2 inhibitors remain doubtful, taking into account the costs of these compounds, but should be considered carefully in the future.

It is obviously necessary to develop and adapt treatment recommendations according to upcoming knowledge all the time. The EULAR recommendations for the treatment of knee OA, however, at the time they were written seemed to summarise all the therapeutic options, including non-pharmacological and surgical options, accurately, even in the light of publications appearing after the end of the literature search in December 1998.

Dr Leeb is currently taking part in a trial focused on the disease modifying ability of CS, sponsored by IBSA.

Author’s reply

I thank Dr Leeb for his interest in my recent letter about the EULAR recommendations.

The recent large, randomised, placebo controlled, doubleblind, double dummy prospective trial had shown that glucosamine sulphate (GS) treatment resulted in significantly less medial joint space narrowing of the knee, in addition to significant improvement in pain and disability, which were sustained for the three year duration of the study. However, the general correlation between symptoms and structural changes was poor. The symptoms of patients with severe joint space narrowing receiving GS did improve, but this was not associated with slowing down of radiographic structure impairment. Further studies with longer follow up are needed to assess whether these changes are predictive of further clinical progression of osteoarthritis.

The year 2000 meta-analysis of the six best controlled trials of chondroitin sulphate (CS) in osteoarthritis had shown better pain relief with CS than with placebo at six months; however, no dose effect was noted (for example, 2000 mg and 800 mg/day were similarly effective). A large long term, double blind, randomised controlled trial is needed to confirm the symptomatic benefit of CS in osteoarthritis.

The main advantage of GS and CS is their safety, and they are certainly more safe than non-selective, non-steroidal anti-inflammatory drugs (NSAIDs), especially in their effect on the gastrointestinal tract.

With regards to COX-1 sparing NSAIDs, I agree with Dr Leeb, that there is no evidence for any important differences in efficacy between them and non-selective NSAIDs.

Systematic reviews have also found no important differences in efficacy between different NSAIDs, but found differences in side effects related to increased doses of NSAIDs and the nature of the NSAID itself.

The principal benefit of COX-1 sparing NSAIDs is that they produce analgesia and anti-inflammatory effects comparable with those of the non-selective NSAIDs but cause fewer symptomatic gastric and duodenal ulcers and fewer gastrointestinal symptoms. The EULAR recommendations need to be revised in the near future.

LETTERS TO THE EDITOR

Fenofibrate: a new treatment for hyperuricaemia and gout?

Allopurinol is the most commonly used drug in the prevention of gout owing to its efficacy and good tolerability. However, some patients still experience hyperuricaemia or gout, or
both, despite allopurinol treatment. Fenofibrate is an established treatment for many common lipid disorders and is unique amongst the fibrinoid acid derivatives because of its ability to lower serum urate by increasing renal uric acid clearance. This urate lowering property has been demonstrated in healthy volunteers and in diabetic and non-diabetic patients with hyperlipidaemia. To date, no studies have specifically evaluated the urate lowering effect of fenofibrate in patients with hyperuricaemia receiving established treatment with allopurinol. We report three cases in which micronised fenofibrate, a single dose formulation of the drug, was initiated in patients with established gout and hyperuricaemia, with and without coexisting hyperlipidaemia. Two of these patients were already receiving established allopurinol treatment.

**PATIENT 1**
A 74 year old Chinese man had recurrent attacks of gout affecting the metatarsophalan-geal joints every two to three months for the preceding three years. He had treated hyper- tension and polygenic hypercholesterolaemia and had been taking allopurinol 300 mg daily for three months, which produced a serum urate range between 0.40 and 0.44 mmol/l. The 24 hour renal uric acid clearance was 6.4 ml/min (reference range 6–11). Treatment was started with micronised fenofibrate 200 mg daily, and three weeks later his urate had fallen by 35% to 0.26 mmol/l, with the 24 hour uric acid clearance rising to 11.5 ml/min (table 1). Alkaline phosphatase activity fell from 77 to 44 U/l, confirming compliance with the fibrate treatment. A temporary withdrawal of fenofibrate treatment for three weeks resulted in an increase in urate to 0.39 mmol/l. Fenofibrate was restarted and he continues to take it in combination with allopurinol. No acute attacks of gout have occurred since fenofibrate was started.

**PATIENT 2**
A 49 year old white man had recurrent episodes of gout affecting the metatarsophalan-geal and knee joints despite having had allopurinol for six months. Micronised fenofibrate 200 mg daily was added to the allopurinol treatment and three weeks later the serum urate had been reduced by 39% to 0.37 mmol/l, with an associated doubling in uric acid clearance (table 1). Additionally, serum lipids were reduced, together with a reduction in alkaline phosphatase activity. Fenofibrate was temporarily discontinued and the serum urate returned to a higher level. It has been restarted and no further attacks of gout have occurred in 12 months of follow up. The doubling in uric acid clearance, which was reversed in two of the patients when fenofibrate was withdrawn, indicates a drug-specific renal effect. The particular large reduction in serum urate in the second patient was perhaps a little surprising, but we are certain that this was largely a fenofibrate effect because a rise in uric acid clearance was seen, together with reductions in alkaline phosphatase activity and serum lipids. Furthermore, he denied any significant lifestyle changes during this period.

Importantly, none of these patients has had any adverse effect, in particular a flare of gout, while taking fenofibrate. Only the second patient wished to take a prophylactic drug against this. Each was advised to increase their fluid intake at the time, though uric acid urolithiasis has not been reported previously with fenofibrate. There has been no evidence of an adverse interaction between allopurinol and fenofibrate in the first two patients, who both continue to take this combination. Although no adverse reactions and interactions should be borne in mind when fenofibrate is prescribed for patients with hyperuricaemia, and measures taken to prevent them considered.

Severe urate lowering can be achieved in patients with established gout and hypertriglyceridaemia. The reductions in urate and serum lipids were of similar magnitude to those seen in patients given the drug who had hyperuricaemia and hypertriglyceridaemia. The reductions in urate were of similar magnitude to those seen in patients given the drug who had hyperuricaemia and hypertriglyceridaemia.

Fenofibrate appears to be a long awaited agent with great potential for use in this condition.
Effect of leeches therapy (Hirudo medicinalis) in painful osteoarthritis of the knee: a pilot study

Leeches therapy was a mainstay in conventional treatment of pain and inflammatory diseases throughout antiquity until the 20th century.1,2 There is now renewed interest in leeches therapy in the field of complementary medicine. Sales of the four principal German traders have increased continuously throughout the past few years and led to an estimated 70,000 treatments (330,000 leeches sold/year, four to five used for each single treatment) yearly in Germany (Roth M, unpublished data). The majority of these treatments aim at pain reduction in regional pain syndromes, mostly for knee osteoarthritis.3,4 With the exception of its application in plastic surgery to maintain blood flow in congested skin flaps,5,6 treatment with leeches has, however, never been evaluated in clinical studies. We, therefore, set up a non-randomised controlled pilot study to assess the onset of action and the impact of leeches therapy as an adjunctive treatment in knee osteoarthritis.

From inpatients whose main diagnosis was severe chronic back pain, we recruited over a period of three months 16 consecutive patients with primary knee osteoarthritis. All patients had had persistent knee pain for more than six months and had definite radiographic signs of knee osteoarthritis without previous injury. Major exclusion criteria were treatment with anti-coagulants, secondary osteoarthritis, substantial comorbidity, and intra-articular corticosteroids in the three preceding months. All patients had an in-hospital period of 14 days and received a health education programme, with focus on exercise, physiotherapy, relaxation techniques, and diet. Regular use of non-steroidal anti-inflammatory drugs was stopped throughout the study period.

After detailed information all patients were offered additional treatment with leeches. Ten patients (eight women, mean (SD) age 69 (9) years, mean body mass index (BMI) 28.0 (4.6) kg/m²) and were treated once with four leeches (Zaug GmbH, Bieberstadt, Germany). Six controls (five women, mean age 68 (8) years, mean BMI 27.3 (3.0) kg/m²) did not wish to be treated with leeches and were treated only conventionally. The leeches were applied by trained doctors topically at the painful knee joint (fig 1), and monitoring was carried out according to published recommendations.7 The primary outcome measure was a change in total knee pain score, assessed by visual analogue scale (VAS, 0 = no pain, 10 = extremely painful) for 10 days daily, starting three days before treatment and, additionally, in a follow up 28 days after treatment.

In comparison with the controls, leech application led to rapid relief of knee pain (p<0.05 three days after treatment, Wilcoxon two sample test), which was most evident seen within 24 hours after application and sustained and clinical relevant improvement after four weeks (p<0.05, Wilcoxon matched pairs test) in the absence of complications (table 1).

The mean length of treatment was 80 minutes, and the procedure was well accepted. There were no serious adverse effects and no local infections. Patients described the initial leech bite as slightly painful. There are several explanations for the observed treatment effect. The saliva of leeches contains a variety of substances such as hirudin, hyaluronidase, histamine-like vasodilators, collagenase, inhibitors of kallikrein and superoxide production, and poorly characterised anaesthetic and analgesic compounds.8,9 Therefore, a regional analgesic and anaphylactic effect by these substances enforced by hyaluronidase as well as counter-irritation might be possible. More importantly, we do not know the non-specific (placebo) effects of this unusual treatment. We observed an apparent mood enhancement during leeching which might explain the observed rapid treatment effect, but hardly explains the lasting pain relief after four weeks.

We recognise the limitations of the present study design as the non-random allocation of treatment, no assessment of functional improvement, and the small sample size. However, we regard the observed clear treatment effect as remarkable; treatment with leeches reduced pain significantly after three days and up to four weeks. The efficacy and safety of this traditional treatment in knee osteoarthritis should therefore be tested in larger randomised controlled trials.

The study was supported by Karl and Veronika Carstens Foundation, Germany.

Clinical features of several connective tissue diseases with anti-Golgi antibody

Rodriquez et al were the first to report autoantibodies directed against the Golgi complex identified in the serum of a patient with Sjögren’s syndrome (SS).5 Since then, several isolated reports have described the

6 Emmerson B. Hyperlipidaemia in hyperuricac-7 70 000 treatments (350 000 leeches sold/year, four to five used for each single treatment) yearly in Germany (Roth M, unpublished data). The majority of these
presence of anti-Golgi antibodies (AGAs) in several connective tissue diseases (CTDs). In addition, immunoblotting and immunoprecipitation studies have suggested that there are at least 14 different Golgi complex autoantigens, and their molecular masses range from 35 to 260 kDa. However, few reports describe the association between the clinical features of CTD and AGAs. In this letter we present a case of rheumatoid arthritis (RA) associated with AGAs and review several reported cases.

The patient was a woman born in 1939 who developed seropositive RA in 1990. She was admitted to our hospital in March 1998 because of high grade fever, cough, sore throat, chest pain, and severe arthralgia. Systemic laboratory examination disclosed no antinuclear antibody, anti-DNA antibody, or anti-Jo-1 antibody. Anti-SS-A antibody was positive. Chest computed tomography showed interstitial pneumonia with fine reticular shadow and honeycombing in both lower lobes. Physical examination showed fine crackles in both lung fields. A laboratory examination showed raised C-reactive protein (78 mg/l), serum aspartate aminotransferase (62 U/l), serum alanine aminotransferase (52 U/l), creatine kinase (236 U/l), lactate dehydrogenase (357 U/l), IgA (3.6 g/l), and IgG (26.2 g/l), and mild interstitial lymphocytic infiltration was demonstrated in a muscle biopsy specimen. Therefore, a clinical diagnosis of RA, polymyositis complicated with interstitial pneumonia was made, in addition to a suspicion of SS.

Figure 1  Indirect immunofluorescence staining of anti-Golgi antibodies just outside the nuclear membrane of Hep-2 cells with the patient’s serum. Crescent-shaped cytoplasmic organella that surround the nuclear membrane of Hep-2 cells, and these were considered to be Golgi apparatus. Linear-shaped cytoplasmic filaments were also seen and considered to be cytokeratins. Western blotting analysis on human epithelial cell line (A549) and hepatoma cell line (HLE) showed that proteins of 58 kDa, 54 kDa, and 50 kDa were stained by the patient’s serum. The 58 and 50 kDa proteins were considered to be Golgi antigens, and the 54 kDa protein was considered to be cytokeratin 8. Tables 1 outlines the clinical features of the 15 patients with AGA reviewed. The patients comprised 11 women, three men, and in one case the sex of the patient was not given. Western immunoblot analyses disclosed several antigens with molecular weights ranging from 50 to 230 kDa.

To date, several possible clinical correlations have been identified in patients with AGA. However, the clinical associations are different; in Blaschek’s report, the incidence of an association with SS was shown to be significantly higher than in patients with other CTDs, whereas Fritzler’s report suggested a strong association with systemic lupus erythematosus (SLE). Our present letter also showed that AGA was detected in patients with SS, SLE, and RA. As clinical features, our patient had mild liver dysfunction as indicated by raised liver enzymes and interstitial pneumonia. Fritzler et al. have also reported that 5/8 patients with AGA had liver dysfunction. In addition, several patients had cardiopulmonary diseases, including pulmonary fibrosis as shown in our case. Because we have shown the existence of antigens in type II epithelial cells (A549) as well as in hepatoma cell lines (HLE), it was speculated that the existence of AGA might be related to liver dysfunction and the onset of interstitial pneumonia. Furthermore, detection of AGA in a patient with RA might also have potential pathogenic implications, because the Golgi apparatus participates in terminal protein glycosylation whereas high levels of agalactosyl IgG occur in RA and correlate with disease activity. In conclusion, our case and those of previous reports suggest that although antigens of AGA have diversity and heterogeneity, AGA might be pathogenetically related to some clinical features of CTDs.

Serum procalcitonin measurement for detection of intercurrent infection in febrile patients with SLE

It is sometimes difficult to distinguish infection from disease flare in febrile patients with systemic lupus erythematosus (SLE). Chill, leucocytosis, and increased C reactive protein (CRP) are known to be markers favouring disease from disease flare in febrile patients with SLE.

We prospectively enrolled 19 patients with SLE with fever who were admitted to Seoul National University Hospital between October 1998 and April 1999. Fever was defined as an axillary temperature over 38°C. Eleven patients with inactive SLE were enrolled as controls. Blood of the febrile lupus patients was withdrawn three times: on the day of the hospital visit, and after 24 hours and 48 hours. Another sample was withdrawn two weeks after defervescence to control infection or because of a decrease in lupus activity. At the time of fever, blood cultures and other necessary cultures were performed with complete blood count, Westergren erythrocyte sedimentation rate (ESR), CRP, serum anti-dsDNA, complements (C3, C4), urine analysis, serum creatinine, and chest x ray examination.

The patients were divided into groups on the basis of viral infection, non-viral infection, and lupus flare. Lupus flare was defined by the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) as an increase of more than three points compared with the SLEDAI of the patient one month before the febrile period. Serum PCT was measured by an immunoluminometric assay (LUMTest, Brahms Diagnostika, Berlin). Twelve lupus patients were shown to have infection (nine non-viral, three viral infections) and seven patients with lupus flare. Non-viral infections consisted of urinary tract infection (n=3), sinusitis (n=1), tuberculosi (n=1), scrub typhus (n=1), pseudomembranous colitis (n=1), aspergillosis (n=1), and nocardiosis (n=1). Viral infections were upper respiratory infection (n=2) and gastroenteritis (n=1).

The white cell count was higher in the group with non-viral infection than in the group with lupus flare (p=0.015, table 1). Westergren ESR increased in 89% of the groups with viral and non-viral infection and in all members of the group with lupus flare. There was no difference between the Westergren ESR of the groups with viral and non-viral infection and lupus flare during the early febrile period (p=0.32). CRP increased in 92% of the group with infection and 89% of the group with lupus flare. CRP tended to be higher in the group with non-viral infection than in the group with viral infection or lupus flare, but this did not reach significance (p=0.98).

Serum PCT in the group with non-viral infection tended to increase continuously or rise gradually in the early febrile period (fig 1). Serum PCT levels in the early febrile period were significantly higher in the group with non-viral infection (mean (SD), 0.98 (0.12) ng/ml) than in the group with viral infection or lupus flare, but this did not reach significance (p=0.98). Serum PCT in the group with non-viral infection tended to increase continuously or rise gradually in the early febrile period (fig 1).

Table 1 Baseline data of 19 patients with systemic lupus erythematosus (SLE) during the early febrile period. Results are shown as means (SD)

CRP rises earlier and is more sensitive than ESR. In this study, CRP tended to increase in the case of non-viral infection, compared with viral infection or lupus flare, but this did not reach statistical significance. Our results indicate that during the early febrile period, serum PCT increased significantly in patients with SLE with non-viral infection compared with patients with lupus flare. Serum PCT decreased after defervescence. These results suggest that serum PCT helps in detecting bacterial or fungal infections during the early febrile period in SLE.

Effect of daily corticosteroid treatment on CRP response to hip or knee replacement in patients with RA

Serum C reactive protein (CRP) is an acute phase reactant which may be continuously increased in patients with persistently active rheumatoid arthritis (RA), or raised only temporarily to a high concentration for a few days as a normal response to uncomplicated hip or knee replacement in patients with osteoarthritis or RA.1 CRP usually decreases in patients with RA when inflammatory activity is treated with daily low dose corticosteroid. This prompts the question whether the CRP response to hip or knee replacement is decreased in patients with RA taking a daily low dose of oral corticosteroid compared with those not taking corticosteroid. This is an important issue because CRP is used as an index to indicate postoperative complications. In this letter we compare the CRP response to hip or knee replacement in two groups of patients with RA: those taking and those not taking oral low dose corticosteroid.

Sixty patients (47 women, 13 men) fulfilling the American Rheumatism Association 1987 criteria for RA, treated at the Rheumatism Foundation Hospital, Heinola, in 1999, underwent hip or knee replacement. Fifty two patients were seropositive. The group receiving prednisolone comprised 44 patients, mean age 62 (SD 8.5) years. The patient group not receiving prednisolone comprised 44 patients, mean age 62 (SD 8.5) years. The prednisolone doses were as follows: four patients received <5 mg daily, 37 had 5–10 mg daily, and three had 12.5–30 mg daily. The patient group not receiving prednisolone comprised 16 patients, mean age 59 (13.4) years.

The CRP concentration was measured by the Randox, United Kingdom, immunoturbidimetric assay. The magnitude of the CRP response was measured by assessing the difference between measurements taken preoperatively and during the first two to one days postoperatively (the time of the peak CRP level) in both patient groups. The CRP responses in the respective groups were compared and statistically evaluated with the Mann-Whitney U test. In the group not receiving prednisolone the preoperative median CRP level was 12 (interquartile range (IQR) 5–26) mg/l, and at day 1 or 2 postoperatively the median CRP had risen to 80 (IQR 53–112) mg/l. In the group in which patients were taking prednisolone the preoperative median was 14 (IQR 6–38) mg/l, the postoperative median 62 (IQR 41–100) mg/l. The difference in CRP response to the operation between the groups was not significant, p=0.15 (fig 1). None of the patients had bacterial infection or substantial haematocto after the operation. The rise in CRP concentration in response to hip or knee replacement was slightly, but not significantly, smaller in patients with RA receiving than in those not receiving prednisolone. Increased CRP concentration was a normal phenomenon in the first few days after hip or knee replacement in these patients with RA and was not altered by low dose prednisolone treatment. This study affords no information as to the CRP response in the presence of postoperative complications, because no such case was encountered. However, we recommend further measures if the CRP concentration remains raised for several days postoperatively and does not decrease steadily.

Lumbar spondylodiscitis secondary to Enterobacter cloacae septicaemia after extracorporeal shock wave lithotripsy

Infections of the lumbar spine may affect either the intervertebral disc or the vertebral body. Most infections of the intervertebral disc occur as an extension of vertebral osteomyelitis or direct inoculations during diagnostic or surgical procedures, or include secondary spondylodiscitis and discitis. This paper reports a case of L5–S1 spondylodiscitis secondary to Enterobacter cloacae septicemia after extracorporeal shock wave lithotripsy (ESWL).

A 52-year-old man presented with side pain, pollakiuria, haematuria, and nocturia. He had been treated with ciprofloxacin for acute pyelonephritis and nephrolithiasis as an outpatient. One week later, the patient was admitted to hospital by the urology department with symptoms of left side pain, fever, chills, shaking, and dysuria. Right renal and right ueter distal lithiasis and right hydronephrosis due to the lithiasis were diagnosed. One week after ESWL the patient was sent to the physical medicine and rehabilitation clinic with chills, shaking, high fever, and low back pain complaints. Lumbar movements were found to be restricted. There was an increase in severe pain at rest. The patient could not stand or walk. No neurological deficit was present. Body temperature was 39°C, pulse 110 beats/min, blood pressure 130/70 mm Hg, breathing 20 breaths/min.

Laboratory findings were as follows: haemoglobin 133 g/l, packed cell volume 0.3/l, white blood cells 18×10³/l, platelets 316×10³/l, erythrocyte sedimentation rate 110 mm/1st h, antistreptolysin O 25 IU, C reactive protein 12.3 mg/l, rheumatoid factor negative. Urine was 14 mg/l of creatinine, uric acid 170 µmol/l. Glucose and electrolytes were normal and serum aspartate aminotransferase was 80 U/l, serum alanine aminotransferase 44 U/l, lactate dehydrogenase 321 U/l, total bilirubin 22 µmol/l, direct bilirubin 10 µmol/l. A considerable number of leucocytes and erythrocytes were noticed in urine microscopy. Enterobacter cloacae was isolated from blood and urine. The isolated pathogen was sensitive to ceftriaxone and amikacin.
**Rheumatic pneumonia**

Rheumatic pneumonia (RP) is a well-described and poorly understood complication of acute rheumatic fever (ARF). It has been reported for more than a century and it has been traditionally associated with a high mortality rate. However, the existence and specificity of primary pulmonary lesions has remained controversial, because similar features may be seen in ARF with complicating congestive failure or uraemia. We report a case of RP that was successfully treated with steroids.

An 18 year old man was admitted to our hospital because of a 10 day history of fever, malaise, and dry cough. The patient had had ARF with carditis at age 7, which resolved without sequelae. A tonsillectomy was performed three years later. Since then, he had received a benzathine penicillin G injection monthly until three years before his actual admission. On admission, physical examination disclosed a temperature of 38.5°C, respiratory rate of 26/min, and rales were heard at the left lower lung. The rest of the examination was unremarkable.

Laboratory values were white blood cells 14.3x10³/l, with 80% neutrophils and 9% band cells, haemoglobin 132 g/l, and platelets 410x10³/l. The erythrocyte sedimentation rate was 90 mm/1st h. Urine analysis, coagulation studies, renal and hepatic function tests, and arterial blood gas value analysis during room air breathing were normal. A chest x-ray examination showed an ill-defined and non-homogeneous area of consolidation at the left lower lobe with a normal cardiac silhouette. As there was a clinical suspicion of pneumonia, acquired in the community, intravenous cefuroxime (750 mg three times a day) and oral roxithromycine (150 mg twice daily) were given.

On the fourth day after admission to hospital, fever and tachypnoea persisted. Consolidation of the air space in the posterior segment of the left lower lobe and pleural effusion were seen on chest x-ray examination and thoracic computed tomography (fig 1).

Thoracentesis yielded a serous fluid containing 1.2x10³ leucocytes/l, with 70% neutrophils, glucose 1.4 mmol/l, protein 27 g/l, and lactate 1 mmol/l.

**Figure 1** Computed tomography scan of the chest showing consolidation in the left lower lobe with associated pleural effusion.
and lactate dehydrogenase 477 IU/L. Doppler echocardiography showed a posterior pericar- 
dial effusion without any other abnormality. Bronchoscopic examination showed inflam-
matory changes in left lower bronchi. There were no neoplastic cells in bronchoalveolar lavage 
specimens. Repeated serological tests for Mycoplasma pneumoniae, Chlamydia pneu-
moniae, Legionella species, cytomegalovirus, and Epstein-Barr virus were negative. Tests for 
antinuclear and anticytoplasmic antibodies, antineu-

tomatoid factor, and antinuclear antibodies were negative, and the serum level of angiotensin 
converting enzyme was normal.

On the 14th day after admission to hospital the patient developed arthritis at the left knee 
and the right wrist. Arthrocentesis showed a turbid fluid which contained 15.2×10^6 leucocytes/l and glucose 1.3 g/l; no crystals were seen. Titres of antistreptolysin O and C reactive 
protein were 400 Toddl units (normal <200) and 1.20 g/l, respectively. Blood, sputum, pleural fluid, bronchoalveolar lav-
age, and joint effusion repeated cultures were negative, and no acid fast bacilli were seen. 
ref.

The antibiotic treatment was discontinued and acetylsalicylic acid (1.5 g four times a 
day) was started. A dramatic improvement in fever and arthritis occurred, though the 
radiological lesion remained unchanged. A pathological examination obtained by thora-
coscopy showed inflammatory changes with 
thickened and fibrosed alveolar septa, and 

nodular aggregates of mature lymphocytes. 

Histological lung specimen obtained by thora-
coscopy showed inflammatory changes with 

intra-alveolar fibroses, so-called Masson bodies. 

It may be difficult to separate the 

contribution of the heart failure or uraemia to 

the RP by itself.

The absence of response to antimicrobial treatment, the 

histological findings, and the response to 

anti-inflammatury treatment favored a diagnos-

is of RP. Despite the fact that salicylates 

have been advocated in the management of 

RP, steroids seem to be the most suitable treatment. 

None the less, deaths have oc-

curred despite the use of this treatment.**

Referrals to an “early 

synovicitis clinic”: are they 

appropriate?

There is mounting evidence that early disease 

modifying treatment improves the outcome 
in patients with rheumatoid arthritis (RA)1 

and that treatment should begin before the 
disease is established and irreversible damage 

has occurred.2 This evidence has led to the 
development of “early synovicitis clinics” in 

many rheumatology units to fast track appro-

priate patients. Early referral for specialist 

advice has been shown to be associated with 

improved health and physical function, with 

the concept of early treatment of RA 

shortening observation periods before refer-

cral in general practice.3 A shortened observa-

tion time is important as Irvine et al4 showed 

that 73% of patients waiting more than one 

year from the onset of symptoms already had 
radiological evidence of erosive change.5

Despite the improved observation times, 

there are few published data showing whether 

referral to early synovicitis clinics is appropri-

ate. We reviewed all referrals (n=156) to our 

early synovicitis clinic at the Royal Victoria 

Hospital, Belfast, which was established in January 

1999, to determine the proportion which were 

appropriate. Referrals to early synovicitis 

clinics were circulated to all general practi-

tioners in the catchment area of the hospital 

(population 600 000) every three months. The 
information was sent by medical press and by 
presentations at general 

practitioner meetings.

Fifty four per cent (n=84) of the 156 

patients were classified as having inflamma-

tory arthritis. Of these patients, 33 were diag-

nosed as RA and disease modifying treatment 

was started. The other diagnoses within the 

inflammatory arthritis group included psori-

atic arthritis, reactive arthritis, ankylosing 
spondylitis, seronegative spondyloarthropathies, 

systemic lupus erythematosus, primary Sjögren’s 
syndrome, and crystal arthritis. Despite the edu-
cational strategies outlined above, a large 

percentage of referrals were inappropriate. 

Forty six per cent (n=72) of patients did not have 
inflammatory arthritis. Of these pa-

tients, 35 had fibromyalgia, 28 had osteoar-

thritis, and nine had another diagnosis within 

the category of soft tissue rheumatism. 

The median time from symptom onset to 

referral was eight weeks and the median time 

from arrival of the referral letter to attend-

ance at the early arthritis clinic was four 

weeks. These results suggest that although the 

message about early referral appears to have 

been successful there were a large number of 
inappropriate referrals.
Factors contributing to inappropriate referrals include:
- The low priority of musculoskeletal disorders in undergraduate training, resulting in poor skills in recognising signs and symptoms of inflammatory arthritis
- The opportunity for faster access to a specialty with long waiting lists
- The broad based referral guidelines which were designed to obtain maximum sensitivity for patients with early RA

To maximise valuable clinic time for patients with early RA and improve the proportion of appropriate referrals we suggest that increased emphasis should be given to the importance of recognition of inflammatory arthritis in undergraduate and postgraduate medical education.

The exploration of new methods of triage in primary care groups by general practitioners with a special interest in rheumatology, or by specialist rheumatology nurses, may also help to improve referrals.

Anti-dsDNA antibodies associated with acute EBV infection in Sjögren’s syndrome

The role of viral infection in the pathogenesis of autoimmune diseases is not clear. Some authors have suggested a role for herpes viruses and retroviruses in the pathogenesis of systemic rheumatic diseases, whereas others have produced evidence against this idea.

In this report we present a case in which an association was found between Epstein-Barr virus (EBV) infection and anti-dsDNA antibodies in a patient with Sjögren’s syndrome.

A 28 year old woman was diagnosed with Sjögren’s syndrome. The clinical presentation included diffuse myalgias, tiredness, and intermittent respiratory complaints. Electrophy showed polyclonal hypergammaglobulinaemia. Antinuclear antibody testing showed a fine speckled nuclear pattern. The antibodies were identified as anti-Ro/SS-A antibodies by counterimmunoelectrophoresis. No anti-double stranded DNA (anti-dsDNA) antibodies were present (Crithidia luciliae assay; Immunoconcepts). Four years after the diagnosis of Sjögren’s syndrome, the patient had an acute EBV infection with persistent tiredness, icterus, and hepatosplenomegaly. The EBV infection was documented by positive heterophile antibodies and the presence of IgM (titre 1/32) and IgG (titre 1/256) antibodies to EBV viral capsid antigen. The antibodies to early antigens were negative (<1/8). The patient did not have IgM rheumatoid factor, which excluded the possibility of a false positive IgM-viral capsid antigen test induced by the presence of rheumatoid factor. Neither antiviral capsid antigen antibodies nor anti-early antigen antibodies had been found one year before the patient presented with the EBV infection. The Crithidia luciliae test was negative two months before the EBV infection. Three months and eight months after the acute infection, respectively, the Farr assay (Ortho Clinical Diagnostics, Amersham, UK) and the Crithidia luciliae assay disclosed anti-dsDNA antibodies. The patients showed no progressive disease and did not develop signs of systemic lupus erythematosus.

The association between EBV and anti-dsDNA antibodies in the case presented here indicates a possible role of the virus in the generation of anti-dsDNA antibodies. The formation of anti-dsDNA autoantibodies may result from the activation of specific B lymphocyte clones or from an imbalance in the regulation of the immune system due to EBV infection. This is consistent with the finding that EBV transformed B cells can produce IgG antibodies with specificity for dsDNA, and with the suggestion that EBV infection may be a causative factor in lupus.
