LETTERS TO THE EDITOR

Primary psoas abscess

Primary psoas abscess is a rare infection with an often vague and non-specific clinical presentation, especially in children. In Asia and Africa 99.5% of all psoas abscesses are primary, compared with 61% in the United States and Canada and 18.7% in Europe. Approximately 70% of psoas abscesses occur in patients younger than 20 years of age, with a male preponderance of 3:1. Fifty seven per cent of psoas abscesses occur on the right side, 40% on the left side, and 3% bilaterally. We present the following case and show the magnetic resonance imaging to emphasise the presenting signs, symptoms, and findings of this unusual infection.

A 13 year old white girl was in excellent health until she developed a dull ache in the superior posterior thigh without radiation. She denied any direct trauma or excessive strenuous activity. Over five days she developed progressively severe, dull pain, localised to the superior posterior thigh with radiation to the back, thigh, inguinal area, flank, knee, and calf. Pain with flexion and external rotation of the affected hip is the most common physical finding.1 A tender palpable mass may be found in the iliac fossa and inguinal area.1–3 Fifty per cent of patients have abdominal tenderness, but guarding and rebound tenderness are uncommon.1 Because of the non-specific pain location, the diagnosis of psoas abscess may be delayed or missed. Differentiation between psoas abscess and hip pathology can be difficult; however, prudent physical examination of the hip can be useful. With psoas abscesses there usually is no discomfort on full flexion of the hip, whereas the presence of hip pathology typically elicits pain.1–3 Laboratory studies are non-specific and typically show leucocytosis, anaemia, a raised erythrocyte sedimentation rate, and, usually, normal urine analysis.1–3

Plain abdominal radiographs occasionally define an outline of the inflammatory mass. Chest radiographs may disclose minimal pleural effusion or raised hemidiaphragm. An intravenous pyelogram may show deviation of the kidney and ureter. Barium studies may disclose bowel loop displacement and associated gastrointestinal diseases.1,4 However, the most accurate diagnostic imaging is computed tomography scan (CT) or MRI, which typically show a low density lesion of the psoas muscle and gas within the muscle itself.1–3 There may be rim enhancement of the abscess wall with contrast medium injection. Definitive diagnosis is made by fine needle aspiration under imaging guidance, and microbial culture of the causative organism.1 If abdominal CT or MRI is unavailable, ultrasonography may demonstrate the inflammatory mass.5 Gallium-67 scanning may be useful in the diagnosis of psoas abscesses and detection of concomitant infectious foci.6 Diagnostic imaging of psoas abscesses shows bacterial infection of the hip, avascular necrosis of the hip, irritable hip, necrotising fasciitis of the psoas muscle, pyelonephritis, pelvic inflammatory disease, retrocaecal appendicitis, S1 herniation, disc, avascular necrosis, vertebral or pelvic osteomyelitis, and epidural abscess.1–3 These entities should be distinguishable upon the correlation of history, physical examination, laboratory tests, and imaging studies.

The cause of primary psoas abscesses remains uncertain. Proposed mechanisms of psoas abscess formation include haematogenous spread from primary infectious foci or local trauma with intramuscular haematoma formation predisposing to abscess development.1 In secondary psoas abscess the most commonly associated disorder is Crohn’s disease; other disorders include appendicitis, colonic inflammatory or neoplasm, disc infections, and a variety of intra-abdominal or retroperitoneal infections.1–3 Primary psoas abscesses are caused by a single organism in 87.5% of cases: pyogenic psoas abscess (88.4%), streptococci (4.9%), and Escherichia coli (2.8%). Blood cultures are positive in 41.7%, usually for Staphylococcus aureus.7 In the past decade the majority of patients with a primary psoas abscess were intravenous drug users (86%) infected with the human immunodeficiency virus (57%).7 Treatment for primary psoas abscess includes percutaneous drainage combined with systemic antibiotic administration.8 Surgical drainage is preferred for the patients in whom the psoas abscess is associated with underlying bowel disease.9 With appropriate treatment, psoas abscess rarely results in death (2.5%).1 Death from psoas abscess in association with other conditions is associated more commonly with inadequate or delayed drainage, or both.1 Patient responded well to antibiotic treatment and recovered completely.

Klippel-Feil syndrome in the prehispanic population of El Hierro (Canary Islands)

Klippel-Feil syndrome is an uncommon anomaly (1:40,000 births), mainly affecting the cervical spine. The classic clinical triad described by Klippel and Feil in 1912—short neck, low dorsal hairline, and restricted neck mobility—is the result of the fusion of a variable number of cervical vertebrae, sometimes reducing their number, and cervical spina bifida. Extraosseus changes, such as hemivertebra, vertebral body clefts, and thoracolumbar abnormalities, are sometimes seen.

In a prehispanic ossuary containing remains of at least 121 subjects in the island of El Hierro (Canary Islands), we noted:

1. A C2-3 block, with both the vertebral bodies and the medial ends of the arches, well preserved right intervertebral foramina, and foramina transversaria (fig 1), and a normal medullar canal. The body of the third vertebra shows intense degenerative signs.
2. A C5-6 block, consisting of two vertebrae with intense degenerative changes fused both by the vertebral bodies and the medial part of the arches. Both cervical blocks seem to belong to the same subject.
3. A well preserved atlas bone, with an incomplete anterior part of the left arch.

with sharp, fine proximal, and distal ends (fig 2A), supporting an underlying developmental defect rather than an acquired one.

4. A left hemiatlas (fig 2B); although it is possible that the right body of the bone was partially fused with the left one (and was not recovered in the archeological excavation), the posterior end of the arch was neither fractured nor fused to any other bony structure, thus pointing to a developmental defect.

Fusion of C2 and C3 (and C5-6), hemivertebra of the atlas, and complete bipartition of the atlas constitute distinctive features of Klippel-Feil disease. Thus the subject with the fused C2-3 and C5-6 blocks and the hemiatlas was probably affected by this disease. Possibly, the second atlas belongs to another subject with the same disease, though this possibility should be cautiously admitted. The two atlas bones show different developmental abnormalities. In the newborn, the ossification of the cartilaginous anterior and posterior arches of the atlas takes place progressively from the already ossified lateral masses. Often, especially in the anterior arch, secondary ossification centre(s) appear. In our case it seems that hypoplastic development of the anterior left arch took place. Because the hypoplastic part of the arch is in its middle part, probably, a second ossification centre was present, but ossification was never completed; in this sense, it is similar to the case described by Chiogira et al, which also showed fusion of C5-6.

The "hemiatlas" perhaps is really an atlas with a midline cleft and a lost half, though the posterior arch does not reach the midline, so it never became fused with the right half of the bone. A secondary posterior ossification centre sometimes appears during the first years of life. In this case, it was absent, in contrast with the anterior secondary ossification centre which was surely present in the former case.

Perhaps familial links existed between the two subjects. Klippel-Feil syndrome is a heterogeneous disorder, showing different alterations in different families. The simultaneous finding of different developmental abnormalities of the atlas in our two cases—assuming that the second one truly represents a case of Klippel-Feil—may either reflect an unusually high prevalence of this entity in the prehistoric population of El Hierro, or may indicate that even in the same family clinical expression of the Klippel-Feil syndrome is variable.

Haematopoietic stem cell transplantation (HSCT) in a patient with Sjögren’s syndrome and lung malt lymphoma cured lymphoma not the autoimmune disease

Haematopoietic stem cell transplantation (HSCT) has been used in an attempt to control autoimmune diseases that respond poorly to conventional treatment, or as a way...
of readjusting the immunological balance.\(^1\) As far as we know, only one case of primary Sjögren's (SS) has been reported,\(^1\) with an unfavourable outcome. Another patient received an allogeneic bone marrow transplant and also had an unfavourable outcome.\(^1\) We describe here a further patient with primary SS who underwent HSCT for a non-Hodgkin's lymphoma affecting the lung (large cell, mucosa associated lymphoid tissue (MALT) lymphoma) and review the literature on the effects of HSCT on the autoimmune features and histopathological changes in primary SS.

**Case report**

A white woman, aged 42, developed recurrent parotid swelling and symptoms of Sjögren syndrome, with a Schirmer's test I of 5 mm in the right eye and 4 mm in the left eye. Break up time was 6 s and sialometry was <1 ml. She had periodic relapses of her parotid swelling. In August 1994 (aged 57) lung x-rays and computed tomography disclosed a parenchymal nodule of 3 cm in diameter in the basal left lobe. She underwent a lobectomy that disclosed a MALT of the large cell type, stage IE. In December 1994 two more nodules in the right lobe, with hilar bilateral adenomegaly, led to the diagnosis of a relapse of her lymphoma, which had progressed to stage IV. She then received six courses of F-MACHOP (vincristine 0.5 mg/m\(^2\) at hours 0 and 12; cyclophosphamide 800 mg/m\(^2\) intravenous (IV) bolus at hour 36, 5-fluorouracil 15 mg/kg IV for six hours at hour 36, cytosine-arabinoside 1000 mg/m\(^2\) IV for six hours at hour 42, doxorubicin 60 mg/m\(^2\) IV bolus at hour 48, methotrexate 500 mg/m\(^2\) IV for six hours at hour 60, prednisone 60 mg/m\(^2\) from day 1 to 14), and ofolic rescue (20 mg/m\(^2\) IV bolus at hours 84, 96, 108, 120), with a prompt reduction of hilar adenopathies and a net decrease of pulmonary nodule size. However, no complete remission was recorded. She was then offered the possible chance of an HSCT. The patient (patient 1) reports the myeloablation, conditioning, recovery, and reinfection of stem cells. After three years of follow up no relapse of the lymphoma has occurred. Sica syndrome after transplantation was unmodified, however, with a persistently poor function of the salivary glands, an unchanged serology (antinuclear antibody titre 1/2560), and an unchanged histopathology (Chisholm-Mason grading = 4) despite having mild fibrosis of the salivary glands.

In table 1 we give the characteristics of the other patient with primary SS (No 2), previously reported. It can be seen that the conditioning regimen, previous treatment, stem cell rescue, and bone marrow reconstitution were different. However, in this case, also, SS was not cured and there was no remission. An immunological reassessment showed persistence of the immunological imbalance and poor function of the salivary apparatus.

Table 2 shows the results for patients with three more common autoimmune rheumatic diseases (rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and scleroderma (SSc)) treated with HSCT and who received an adequate follow up.\(^2\) A total of 270 such patients are registered so far in the European Bone Marrow Transplant/EULAR database, but the number who have received adequate follow up is much smaller.

Current data suggest that best results have been obtained in RA, the worst in SSc, suggesting that T helper 2 oriented diseases have a poorer response.

Results for SS seem to confirm this because HSCT cured lymphoma but did not improve the autoimmune disease. No changes were recorded in the function of salivary glands, or in the synthesis of ANA, or the histopathology. The other case reported did show some early improvement in the function of the glands, but no improvement afterwards and an infection leading to death. Early recurrence of autoimmune features and of autoantibodies was seen in patients with SLE and CREST.\(^3\) We do not know whether various conditioning regimens or myeloablation approaches (with or without T cell depletion) might result in different outcomes. It seems unlikely that T cell depletion would offer a better prospect, especially in view of the increased risk of long term immunosuppression, lymphoproliferative diseases, and infections. On the other hand, allogeneic bone marrow transplantation, even though clearly appealing given the chance of eradicating the intrinsic stem cell defect,\(^4\) does not represent a definite cure either and the related morbidity-mortality still remains too high to be accepted as a possible alternative. As benefits have been seen in around two thirds of the cases treated so far, controlled trials in the three major rheumatic diseases are eagerly awaited.

We gratefully acknowledge the invaluable help we received from Professor A Tyndall, who provided us with the latest data available of the EBMT/EULAR registry on haematopoietic stem cell transplantation in autoimmune diseases.

5 Euler JH, Marmont AM, Bacigalupo A, Fastenrath S, Dreger P, Hoffmecht M, et al. Primary and secondary bone marrow transplantation, even though clearly appealing given the chance of eradicating the intrinsic stem cell defect,\(^4\) does not represent a definite cure either and the related morbidity-mortality still remains too high to be accepted as a possible alternative. As benefits have been seen in around two thirds of the cases treated so far, controlled trials in the three major rheumatic diseases are eagerly awaited.

We gratefully acknowledge the invaluable help we received from Professor A Tyndall, who provided us with the latest data available of the EBMT/EULAR registry on haematopoietic stem cell transplantation in autoimmune diseases.

Castleman’s disease

A 65 year old woman presented in February 1998 with joint pains, mild weight loss, and a low grade irregular fever. Initially, pain was localised around both shoulder joints. Subsequently, elbows, wrists, hips, and knees were affected, with morning stiffness, but without particlar malaise. The symptoms were accentuated by movement, but also persisted during the night, often keeping the patient awake. On clinical examination, there was limited painful movement of the shoulders and hips, with a marked reduction in strength. The small joints of the hands and feet were not affected. No other pathological conditions were found. Laboratory findings showed a marked increase in erythrocyte sedimentation rate (ESR, >100 mm/1st h), hyper-gamma globulinaemia and a mild anaemia, whereas enzymatic activity (serum aspartate aminotransferase, serum alanine aminotransferase, alkaline phosphatase, lactate dehydrogenase, and creatine kinase) was within the normal range. A diagnosis of polyclonal gammaglobinaemia was made and a rapid and marked clinical improvement was obtained with low dose steroid treatment (prednisone 12.5 mg/day). Pain disappeared, muscle strength and joint function became normal within a week. A decrease in ESR (to 40 mm/1st h) and α1 globulinaemia was noted after one month. The clinical condition remained satisfactory during 1998, with a complete normalisation of ESR and α1 globulinaemia after three months.

In January 1999 she developed jaundice with pruritus and a subcontinuous fever (38.5–39°C). Axial tomography and nuclear magnetic resonance disclosed compression of the biliary duct by a compact, well defined retropancreatic mass (about 4 cm in diameter). Laboratory pattern was typical of cholestasis (hyperbilirubinaemia, increased serum alkaline phosphatase activity). Endoscopic retrograde colangiopancreatography showed slight enlargement of the biliary tract, dilatation of the gall bladder walls, and absence of gall stones. Transist of contrast medium along the biliary tract slowed down.

Explorative laparotomy confirmed the presence of a mass compressing the common bile duct. This was removed and histological examination disclosed a lymph nodal architecure characterised by evident follicular hyperplasia. Some of the germinal centres were enlarged and comprised polymorphous follicular centre cells, whereas other germinal centres were depleated of lymphocytes, and consisted predominantly of dendritic reticular cells showing vascular proliferation. The mantle zone was expanded and concentrically arranged around the atrophic germinal centres (onion skin layers). The interfollicular areas were also prominent, containing small lymphocytes, occasional eosinophils, plasma cells, and some immunoblasts, and showing numerous hyperplastic vessels of the postcapillary venous type. Occasionally these vessels, which were often hyalinised, penetrated the expanded follicles perpendicularly, giving rise to the so-called “lollipop” appearance (fig 1). An immunocytochemical study confirmed the normal organisation of the nodal structures, with a clear positivity of follicular elements for typical B cell markers CD20 and CD79a, and positivity of interfollicular lymphoid elements for T cell markers CD3 and CD45R0, whereas the dendritic reticular cells showed a typical positivity for CD21.

These features are distinctive of Castleman’s disease, also known by the descriptive term angiofollicular lymph node hyperplasia. This is a clinicat entity characterised by angiofollicular hyperplasia of the lymph nodes without the presence of any atypical cells or other signs of malignancy. Many (multicentric or systemic form) or single (monocentric or solitary form) lymph nodal groups can be affected in the process and two histological subsets have been recognised: a hyaline-vascular type, characterised by marked expansion of the mantle follicular zone and a plasma cell type, with diffuse plasma cell proliferation in the interfollicular tissue. The cause of the disease is unknown, but overproduction of interleukin 6 has been shown in the course of Castleman’s disease and a possible pathogenic role for this cytokine has been suggested. It is commonly associated with several autoimmune conditions such as systemic lupus erythematosus, Behçet’s disease, amyloidosis, and with various neoplastic diseases, but its onset during the course of polymyalgia rheumatica has not been recently reported. No data exist about the possible relation between Castleman’s disease and polymyalgia, but a role for interleukin 6 can be suggested, perhaps through a stimulating action of this cytokine on monocytes and lymphocytes. The present case can be considered typical of the solitary form, hyaline-vascular type of Castleman’s disease. Our patient did not present any other lymphatic disease during the subsequent months, which would seem to confirm the good prognosis of this disease.
