Pulsed electromagnetic field therapy in the management of knee OA

It seems most unusual that in a review of “all currently available treatments” for knee osteoarthritis (OA) by 21 authorities and “two experts in the field of guidelines methodology”, pulsed electromagnetic field therapy was not mentioned in the text or the 51 references. This is particularly troubling because over 2800 publications between 1966 and 1998 were retrieved. An identical search for efficacy of magnetic field therapy during this period listed 31 studies with at least one control group, including two double blind trials citing benefits in knee OA from a peer reviewed arthritis journal. In 1999 over 50,000 patients received pulsed signal therapy (PST) prescribed by over 1000 doctors at more than 300 clinics and hospitals in 16 countries, where it is usually reimbursed by fiscal intermediaries because of its proven record of cost effectiveness and safety. A summary of PST double blind and randomized study results over 50,000 patients has been published, and findings in 100,000 patients (the vast majority with knee OA) have also been reported at recent international conferences. Although “alternative” remedies, ranging from minerals, vitamins, nutritional supplements, and capsaicin and diclofenac gels to sex hormones were discussed, in contrast with PST, none satisfied the category criteria the panel established to determine strong recommendation. Nor do any have the solid basic science studies that PST provides with its in vitro support for mechanisms of action to explain efficacy based on proteoglycan synthesis and chondrocyte stimulation results.

Pulsed signal therapy is the result of three decades of research designed to characterise the piezoelectric signal that normally stimulates chondrocyte activity by creating a stimulation potential in the extracellular matrix when bone is subjected to pressure. Although the transmission of this signal is impaired in OA, PST can reproduce this signal. The Bioelectromagnetics Society 22nd Annual Meeting Abstracts Book, 2000:76.

This is particularly troubling because over 2800 publications between 1966 and 1998 were retrieved. An identical search for efficacy of magnetic field therapy during this period listed 31 studies with at least one control group, including two double blind trials citing benefits in knee OA from a peer reviewed arthritis journal. In 1999 over 50,000 patients received pulsed signal therapy (PST) prescribed by over 1000 doctors at more than 300 clinics and hospitals in 16 countries, where it is usually reimbursed by fiscal intermediaries because of its proven record of cost effectiveness and safety. A summary of PST double blind and randomized study results over 50,000 patients has been published, and findings in 100,000 patients (the vast majority with knee OA) have also been reported at recent international conferences. Although “alternative” remedies, ranging from minerals, vitamins, nutritional supplements, and capsaicin and diclofenac gels to sex hormones were discussed, in contrast with PST, none satisfied the category criteria the panel established to determine strong recommendation. Nor do any have the solid basic science studies that PST provides with its in vitro support for mechanisms of action to explain efficacy based on proteoglycan synthesis and chondrocyte stimulation results.

The evidence based approach—of which I would like to deal. As we know the dose of low molecular weight heparin in pregnant patients with APS, I believe that the dose of low molecular weight heparin has to be adjusted in individual patients. The measurement of anti-factor Xa activity in plasma enables us to calculate the dose of low molecular weight heparin which is needed to achieve optimal inhibition of the coagulation cascade. Values of 0.6–1.0 U/ml are believed to give maximum protection against thromboembolic events. From my experience the optimal dose of low molecular weight heparin may be different in different patients. Moreover, over the last few years, given once daily rarely guarantees the desired value of anti-factor Xa activity and often a second injection has to be applied to achieve optimal effect. Therefore, as long as controlled data are missing I would suggest that the measurement of anti-factor Xa activity in pregnant patients with APS should be used to adjust the dose of low molecular weight heparin. This may result in better protection of mother and fetus in this disease.
Caudal epidural injections

Price et al recommend that caudal epidural injections should be carried out with x-ray screening.1 In practice the technique of performed in the outpatient clinic, where screening facilities are not usually available.

I have reviewed the outcome of 44 unscreened caudal epidural injections given to 34 patients in my outpatient clinic in the 12 months from July 1999 to June 2000. Patient selection was made on the basis of unilateral nerve root pain in the leg in the presence of symmetrical straight leg raising. Nine patients had asymmetrically reduced straight leg raising and four of those with full straight leg raising had pain in the L4 dermatome, mostly with a positive femoral nerve stretch test on the affected side. Spinal mobility and the presence or absence of a neurological deficit did not influence the decision to offer an epidural injection.

The procedure was carried out with the patient lying prone on the examination couch. After thorough skin preparation and a local injection of 2 ml lidocaine (lignocaine) 2%, 40 mg triamcinolone hexaconotide mixed with 10 ml lidocaine 0.5% and 10 ml normal saline was injected into the epidural space through the sacral hiatus with a 20G spinal needle. The patient was subsequently kept prone for 30 min and remained horizontal for a total of 60 minutes before being allowed home.

Six of the patients were subsequently given a second epidural injection and two of them received three to six further injections. The procedure was repeated only if there was a satisfactory response to the original injection. For the purpose of this audit, outcomes were graded as:

1 Complete or substantial relief of root symptoms for a minimum of three months.

2 Temporary relief for between one week and three months.

3 A sustained partial response (up to 50% reduction in pain).

4 No response (negligible pain relief or pain reduced for less than one week).

After the first epidural injection, 13 patients were cured of their root pain or obtained relief for three months or more, six derived temporary relief, four partial relief, and 10 showed no response. One of the non-responders was subsequently deemed to have Achilles tendinitis rather than S1 root pain. The outcome in the remaining case is unknown as the patient defaulted from follow up.

Of the eight patients who received a second epidural injection, three were cured or had sustained relief, three partial relief, and two did not respond (despite previous satisfactory responses for four and nine months, respectively). Of the two patients who were given a third epidural injection, one enjoyed sustained relief of pain while the other had temporary relief for six to eight weeks.

In brief, 23/34 (68%) of patients experienced at least a temporary or partial response to the initial unscreened caudal epidural injection and of the eight patients who were given either two or three epidural injections, four obtained sustained relief from their leg pain.

There were no complications from the procedure. On further analysis of the results, 68% of patients with full straight leg raising showed a least a temporary response to the first epidural injection compared with 44% of those with asymmetrically reduced straight leg raising. Of patients with neurological deficit, 85% experienced at least temporary pain relief.

Sixteen patients (47%) were ultimately referred to the chronic pain management services for nerve root blocks and three (9%) for a surgical opinion on the basis of the results of a magnetic resonance imaging scan of their lumbar spine. Although x ray guidance theoretically might improve the accuracy of placement of the spinal needle, these results show that caudal epidural injections can be carried out safely and effectively in an outpatient setting without radiological screening. This also ensures prompter treatment for the patient.

Interleukin 1 gene polymorphisms

I read with interest the recent article by Grilly and colleagues1 on the potential use of interleukin 1 (IL1) gene polymorphisms in predicting the need for joint surgery in patients with rheumatoid arthritis. Although the authors’ findings are certainly intriguing and worthy of further investigation, I would like to raise a couple of points as to how these were arrived at in the first place.

When adopting the “candidate gene” approach in any disease association study, it pays to consider carefully the physiological context of a hypothesis. In this case the authors worked on the premise that one of the IL1 gene family polymorphisms investigated might correlate with disease outcome. These included polymorphisms both in the IL1 genes and the IL1 receptor antagonist (IL1ra) locus. The IL1ra is unique in being the only known endogenous cytokine receptor antagonist. The genes encoding IL1a, β
and the IL1ra have co-evolved as a cytokine control mechanism: agents eliciting IL1 production generally induce IL1ra gene transcription as well, either directly or through a feedback loop triggered by IL1 itself. IL1ra competes with IL1 for binding to the cognate receptor, but produces no known signalling events upon binding. Additionally, one of the two IL1 receptors, type II, also lacks any known signalling capacity and is thought to function as a decoy binding site. If it is assumed that polymorphisms found in various members of the IL1 gene family modify gene function then the implication is that they should be studied collectively, not individually. In support of this argument comes recent experimental evidence showing that two IL1-ra levels are determined free from allelic combinations within the IL1 gene family, as well as evidence for linkage disequilibrium between polymorphic markers spread across the IL1 gene family locus. It is fair to say that Crilly and colleagues did allude in their paper to the possible existence of an extended IL1 gene family haplotype. However, there is already sufficient published evidence to justify examination of haplotypic combinations of the investigated alleles in population studies.

On a different note, although the authors’ argument about the validity of surgery as a study end point is convincing, their selection of a 15 year disease duration free from surgery as the cut off time point for this study seems dubious. A previous study by the same group had calculated that the median disease duration before surgery was 14.6 years, implying that there are a substantial number of patients in the “no surgery” group who will require surgery shortly after the 15 year time point, thereby potentially confounding any significant statistical findings. One might argue that the aim of this study was not to differentiate between patients that will or will not require surgery but, rather, to differentiate between rapid (<15 years) versus delayed (>15 years to surgery) disease progression. Even so, a more valid statistical approach might have been to analyse all patients as a single group and try to correlate genotype (or haplotype) with disease duration to surgery.

J. VAMVAKOPOULOS
University Department of Surgery, Addenbrooke’s Hospital, Cambridge, UK

**Author’s reply**

I thank Dr Vamvakopoulos for his interest in our article1 and would like to make the following response.

We agree that testing for haplotype combinations of the interleukin 1 (IL1) gene family allele would be useful. However, for a large number of alleles to be tested a considerable sample size would be needed to correct for multiple allele testing. This would require a multicentre study; this is limited by funding constraints.

Secondly, for the statistical analysis we predefined early and late surgery. Analysis was undertaken after discussion with a qualified medical statistician. Should the correspondent wish to analyse our data, we would be happy to allow access if guarantees can be provided.

**LETTERS TO THE EDITOR**

**A case of shingles mimicking carpal tunnel syndrome**

A 59 year old woman with an eight year history of seropositive erosive rheumatoid arthritis (RA) receiving sulfasalazine and penicillamine presented with severe sudden onset pain radiating from the left elbow to the left thumb, index and middle fingers. Examination disclosed synovitis of the left wrist, which might have caused median nerve compression. The wrist joint was injected with 20 mg of triamcinolone acetate with 1% lidocaine (lignocaine). She returned the following morning complaining of worsening pain. She was clinically well with no fever. White cell count was normal, but the erythrocyte sedimentation rate (ESR) was raised at 73 mm/1st h. A transcutaneous nerve-stimulating machine was applied and she was prescribed amitriptyline 25 mg at night. The following day she had improved significantly but had developed a vesicular rash in the C6 dermatome consistent with herpes zoster infection (fig 1). Viral titres were consistent with current varicella zoster infection.

**DISCUSSION**

Establishing the cause of pain in patients with RA can be notoriously difficult. In addition to the psychological factors that influence pain perception, wrist and hand pain may result from rheumatoid synovitis, soft tissue inflationation, or mechanical nerve compression at wrist, elbow, and cervical spine. Herpes zoster infection is heralded by burning discomfort in a dermatomal distribution, which may occur for up to five days before the onset of the typical rash. Cervical dermatomes are affected in up to 15% of patients1 and may result in diaphragnatic paralysis and lower motor neurone paresis.2 In this case the occurrence of prodromal symptoms of herpes zoster mimicked the symptoms of carpal tunnel syndrome, presumably secondary to RA synovitis.

RA increases the risk of herpes zoster infection.3 In one series the use of low dose methotrexate, long duration of disease, and seropositivity were risk factors for subsequent infection.4 Gold treatment may also increase the likelihood of shingles.5

Immunocompromised patients should receive acyclovir early to avoid viral dissemination. In patients with RA the complexity of the differential diagnosis may delay diagnosis unless the possibility of herpes zoster infection is kept in mind.

**Conflict of interest: none.**

fevers, gastrointestinal disturbances of nausea and vomiting, granulocytopenia, and hepatic cellular injury. More rarely, hypersensitivity can present with features of severe systemic infection and end organ dysfunction.\(^1\) Azathioprine is a commonly used immunosuppressive drug and is used in many medical specialties. Therefore recognising azathioprine hypersensitivity is important for all doctors. We report a case in which we suspect such an azathioprine hypersensitivity reaction.

A 32 year old Asian woman with mixed connective tissue disorder presented with a one day history of general malaise, fevers, and painful digits. Fourteen days earlier treatment had been started with azathioprine 50 mg daily, and her prednisolone increased from 5 mg to 15 mg daily owing to the development of proteinuria (1.5 g on 24 hour urine collection) and urticarial vasculitis on her lower legs.

On examination she was shocked, with a blood pressure of 70/30 mm Hg and had marked acrocyanosis (fig 1). The differential diagnosis included a lupus crisis or septic shock. She was treated in the intensive care unit with intravenous ceftriaxone, metronidazole, and prostacyclin for digital ischaemia after serial cultures were taken from all major sites. Staphylococcal toxic shock was excluded, with no growth on vaginal swabs and a negative staphylococcal toxin test. After negative cultures 1 g methylprednisolone was given for a possible flare up of her connective tissue disease. The azathioprine was discontinued. She improved despite concomitant intravascular coagulation. Multiple cultures from all sites did not identify any source of sepsis.

We suspected azathioprine hypersensitivity owing to:
- The timing of the patient’s illness in relation to the initiation of azathioprine
- The presence of recognised features of hypersensitivity—fever, chills, diarrhoea, hypotension, and hepatic dysfunction
- The effect of rechallenge. Three weeks after the presenting episode, one dose of azathioprine 25 mg was given for steroid-sparing effect (the initial illness was attributed to disease flare up); the patient had a more severe and rapid hypersensitivity response requiring treatment with intravenous immunoglobulin and haemofiltration in intensive care.

She improved after treatment with high dose corticosteroids. No cultures ever isolated an infective source.

This case shows the importance of recognising azathioprine hypersensitivity. Approximately 50 cases have been reported in patients with immune mediated diseases such as inflammatory bowel disease, multiple sclerosis, and immune thrombocytopenia, where the initial illness is often ascribed to sepsis or reactivation of underlying disease. Most reactions occur in the first four weeks of drug initiation.\(^1\) Hypersensitivity should always be included in the differential of fever, hypotension, and renal failure. The case was reported to the Committee on Safety of Medicines (United Kingdom).

The mechanism of the reaction is unclear. Azathioprine is composed of a nitroimidazole attached to 6-mercaptopurine. It is proposed that the imidazole component causes hypersensitivity, while the 6-mercaptopurine may cause haematological side effects. However, there are conflicting reports about the component of the drug to which the hypersensitivity reaction can be attributed.\(^1\) Fields reviewed 49 cases, where the reaction occurred equally in men and women, aged 16–76 years, and there was a wide variation in azathioprine doses.\(^6\) All patients who developed shock were also taking corticosteroids.

Support for an allergic reaction is that it occurs in only a small percentage of patients,\(^4\) and the event recurs with drug rechallenge, as occurred inadvertently in our patient. Rechallenge with azathioprine is therefore dangerous and should be done under careful observation. A hapten from the imidazole component may bind to a protein molecule to elicit type 1 hypersensitivity. Reactions mimicking sepsis may result from increased production of mediators such as tumour necrosis factor.\(^1\)

**Figure 1**  (A) A view of the patient’s feet three weeks after the initial presentation, showing demarcating digital ischaemia; (B) a close up view showing marked digital peripheral ischaemia.
Immunosuppressive treatment for vasculitis associated with Lyme borreliosis

Vasculitis of the central nervous system is a rare complication of Lyme borreliosis. We now report a case of early onset borrelia associated encephalitis followed by systemic vasculitis. Antibiotics failed to improve the clinical course and remission was only reached after extensive immunosuppressive treatment.

A 52 year old man was admitted because of fever, headache, tinnitus, and painful joints. He reported a tick bite on his left arm, which had occurred three weeks earlier and which was followed by a reddish skin eruption. His general practitioner started treatment with doxycycline, but the patient’s condition worsened. The patient had a fever of 39.9°C, leucocyte count of 16.1×10⁹/l, routine blood analysis was normal. Cultures (blood, urine, stool) were negative. Enzyme linked immunosorbent assays (ELISAs) showed an increased anti-borrelia-IgM titre of 322.2 EU/ml (normal <30) with normal IgG levels, suggestive of early stage Lyme borreliosis. This was supported by western immunoblotting, with spirochaetes therein suggesting an autoimmune basis for vasculitis.

Matters arising, Letters

Shortly upon arrival at the ICU the patient was intubated and mechanically ventilated because of respiratory insufficiency due to muscle fatigue. Examination now disclosed numerous splinter haemorrhages distributed over the whole body. Ceftriaxone was continued for 10 days and then replaced by doxycycline. After 18 days antibiotic treatment was discontinued because of lack of improvement. Fever persisted and generalised epileptic seizures complicated the course. Cultures remained negative. An ELISA was repeated after four weeks: the anti-borrelia-IgM was then raised to 800 EU/ml; the IgG level was also above normal. The number of splinter haemorrhages increased and a non-oliguric renal insufficiency developed, resembling a glomerulonephritis with microscopic haematuria, granular casts, and proteinuria (0.9 g/24 h). Screening markers of autoimmune diseases (antineutrophil cytoplasmic antibodies, antinuclear antibodies, cryoglobulins) were negative. A skin-fascia-muscle biopsy sample taken from the right leg showed vasculitis of medium sized arteries (fig 1). No spirochaetes were detected in this sample. Treatment with prednisolone (1 mg/kg/day) did not improve the condition of the patient within one week, therefore, cyclophosphamide (2 mg/kg/day) was added. Within two days the patient regained normal neurological functions. Renal function improved within four weeks (serum creatinine decreasing from 249 to 130 μmol/l, blood urea nitrogen decreasing from 56.4 to 24.4 mmol/l of urea) and the patient was weaned from the ventilator. Follow up was uneventful.

Vasculitis may develop within weeks after infection and complicate the clinical course of Lyme borreliosis. To our knowledge, this is the first description of a systemic vasculitis including cerebral and renal disease after B burgdorferi infection in a human being. Histological proof for vasculitis was assessed in a skin-fascia-muscle sample; the absence of spirochaetes therein suggests an autoimmune based pathogenesis. As in this case, laboratory support for acute B burgdorferi infection is an important issue, especially in areas like the Netherlands. Whether elicited directly by the micro-organism or by secondary autoimmune mechanisms, vasculitis occurs in association with disseminated organ failure. Cyclophosphamide, successful in a case of B burgdorferi induced cerebral vasculitis, was effective for this case of systemic vasculitis as well.

In conclusion, persisting vasculitic activity should be suspected whenever antibiotic treatment does not improve the clinical course in Lyme borreliosis. When borrelia associated vasculitis has been histologically established, and does not respond to corticosteroid treatment alone, we suggest the combined use of prednisolone and cyclophosphamide.

Bilateral transient osteoporosis of the knee in pregnancy

Transient osteoporosis of pregnancy involving the hips has been reported widely. The knee is much less commonly affected and only isolated cases have been reported. We report the case of a woman in the third trimester of pregnancy with bilateral transient osteoporosis of the knees.

Figure 1 Skin-fascia-muscle biopsy sample showing vasculitis of a medium sized artery and some necrosis of the vessel wall.

www.amrheumdis.com
A 36 year old woman presented with a one month history of pain in the left knee followed a week later by pain in the right. The right knee deteriorated over one to two weeks until she was unable to weight bear. There was no pain at rest. At the time of presentation she was 30 weeks pregnant with her first child conceived through in vitro fertilisation. There was no past history of joint problems, alcohol excess, corticosteroid use, preceding trauma, acute medical illness, or any constitutional symptoms. She walked with two crutches. Joint examination showed a slightly warm right knee with no clinical evidence of an effusion. Both knees were non-tender to palpation but painful at maximal flexion.

Investigations showed an erythrocyte sedimentation rate of 33 mm/1st h, C reactive protein slightly raised at 10 mg/l (normal <3), and globulins at 36 g/l (25–35) with a normal albumin. Full blood count, and globulins at 36 g/l (25–35) with a normal albumin. Antinuclear antibodies, rheumatoid factor, and HLA-B27 were negative. Plain radiography of the left knee showed extensive oedema in the medial and lateral femoral condyles and some oedema in the surrounding soft tissues of the right knee (fig 1). There was an effusion in the suprapatellar bursa and some synovial proliferation. In the left knee there was a moderate amount of oedema in the medial femoral condyle and a trace of oedema in the medial tibial condyle.

A diagnosis of transient osteoporosis of pregnancy was entertained and the patient was treated with simple analgesics and followed up closely throughout the remainder of her pregnancy. She presented to the delivery suite in labour at 39 weeks' gestation and successfully delivered a healthy 4500 g male infant by fast normal vaginal delivery. By 4 days post partum the baby began to crawl and she could walk without any aids. At three months post partum there was only residual discomfort in the right knee walking up and down stairs. Repeat MRI of the right knee was performed three months post partum and showed improvements in bone marrow oedema. In the right knee there was only minor patchy oedema in the distal femur and proximal tibia. In the left knee there was some residual spotty marrow inhomogeneity in the lateral tibial plateau.

Transient osteoporosis is an uncommon condition affecting middle aged men or women in the third trimester of pregnancy. The hip joints are most commonly affected, being reported in 76% of cases. There are only isolated case reports of the knee being affected in pregnant women, and none with both knees involved as in this report.

Plain radiography of the affected joint is often normal early in the course of disease, with changes only becoming apparent after four to six weeks. Demineralisation of the bone and resultant osteopenia may be severe. Joint space is preserved throughout the course and there is no progression to joint erosion. MRI is the radiological investigation of choice showing transient bone marrow oedema (the term preferred to “transient osteoporosis”) and almost always a joint effusion. The cause is unknown, but the MRI appearances and limited histological information suggest an active inflammatory process. Although a variety of treatments have been used, a conservative approach is favoured during pregnancy.
(ACHA) levels in patients with various atherosclerotic vascular disorders. In this study ACHA levels of patients with SLE were compared with those of healthy donors.

Sixty eight patients (64 women, four men), aged 42.6 (8.12), were SLE did not di (81) AU/ml) or inactive (64 (38) AU/ml) High ACHA levels, in the upper quartile with SLE was significant (p<0.001) (fig 1).

Sixty eight patients (64 women, four men), aged 42.6 (8.12), were enrolled into the study. The SLEDAI (SLE Disease Activity Index) score was used to measure disease activity. Patients were considered to have active lupus if they scored at least 2 on the modified SLEDAI scale (calculated by omitting anti-dsDNA and complement C4, data not shown). No significant differences were found between patients treated with corticosteroids for inactive disease or those with inactive disease and not receiving corticosteroid treatment (p=0.174). The latter group had not received corticosteroids for at least one year before blood samples were obtained. The difference between the ACHA levels of patients who had or had not experienced vascular events was not significant.

The observed increase of ACHA levels was measured by a solid phase enzyme immunoassay described earlier. Poly styrene plates (Greiner, Frickenhausen, Germany) were coated with 5 µg/well cholesterol dissolved in 100 µl absolute ethanol and incubated at 4°C for 24 hours. After washing with phosphate buffered saline (PBS) and blocking with 0.1% casein (Reanal, Budapest, Hungary) in PBS, the wells were incubated with 100 µl samples of serum diluted 1:800 in PBS containing 0.1% casein. The binding of ACHA was detected by anti-human horseradish peroxidase conjugated γ-chain-specific rabbit antibodies (DAKO, Glostrup, Denmark) and with o-phenylenediamine (Sigma, St Louis, USA) using H₂O₂ as substrate. Optical density was measured at 492 nm (reference at 620 nm), and the mean of duplicates was calculated. Serial dilutions of purified immunoglobulin were used as standards in all experiments. Data obtained as optical density values were expressed in arbitrary units per millilitre (AU/ml), related to the standard curve. Our previous observations, in accordance with those of others, demonstrated the specificity of ACHA to cholesterol. The inter- and intra-assay variations of this method were 18.7% and 9.5%, respectively.

Differences between the parameters measured in controls and patients with SLE, between patients with active and inactive SLE, and those between patients with and without previous vascular events were calculated using the Mann Whitney- test. The χ² test was used to estimate the discriminatory power of ACHA between patients with SLE and healthy donors. The correlation of individual parameters with each other and healthy donors. The correlation of individual parameters with each other and healthy donors was assessed by using the Spearman's rank correlation test.

Twelve samples (18%) were classified as having been obtained from patients with active SLE and 56/68 (82%) from patients with inactive disease. Three of the 12 "active" samples were from patients with SLE in more than one organ system and nine were from patients with disease activity in one organ system only (myositis, four), central nervous system (two), renal (two), and cutaneous (one). The difference between ACHA levels measured in the control group and in patients with SLE was significant (p<0.001) (fig 1).

High ACHA levels in the upper quartile occurred in 29/68 (43%) patients with SLE and 13/60 (22%) controls (p=0.012). ACHA levels (mean (SD)) of patients with active (97 (81) AU/ml) or inactive (64 (38) AU/ml) SLE did not differ significantly (p=0.21) and did not correlate with the SLEDAI score.

**Figure 1** Individual anticholesterol antibody (ACHA) levels (mean (SD)) of patients with systemic lupus erythematosus (SLE) (69 (49) AU/ml) and of healthy donors (38 (34) AU/ml). Horizontal lines show median values. (r=0.22, p=0.066). No correlation was found between the ACHA levels and other parameters (such as anti-dsDNA, CH₅₀, C₃, and C₄, data not shown). No significant differences were found between patients treated with corticosteroids for inactive disease or those with inactive disease and not receiving corticosteroid treatment (p=0.174). The latter group had not received corticosteroids for at least one year before blood samples were obtained. The difference between the ACHA levels of patients who had or had not experienced vascular events was not significant.

The observed increases of ACHA levels may be related to underlying chronic inflammatory disease. A number of conditions such as dyslipoproteinemia, nephritic syndrome, and changes in cholesterol membrane domains might have elicited the increase of ACHA levels. Corticosteroid treatment might have stimulated ACHA production, though according to our observations this intervention does not alter ACHA levels significantly. A preventive role against atherosclerosis in patients with SLE may be attributed to raised ACHA levels, though these may also exert an atherogenic effect.

Further studies are necessary to clarify the role of ACHA in the changes of lipid metabolism ascertained in patients with SLE.

Intravenous immunoglobulin for treatment of gastro-intestinal haemorrhage in dermatomyositis

Polyarthritis (PM) and dermatomyositis (DM) are systemic inflammatory disorders affecting skeletal muscles and other organs, especially the digestive tract. Oesophageal motor disturbances are common, occurring in as many as 25–60% of patients with PM/DM. Gastrointestinal disease is less recognised in PM/DM, though it may be responsible for life threatening complications—for example, dramatic haemorrhage, perforation, pseudo-obstruction, pneumatoasis cystoides intestinalis, and spontaneous abdominal haematoma. We recently observed a new case, which is of particular interest. The patient who had DM refractory to steroids and both gastrointestinal haemorrhage related to vasculitis and oesophageal impairment due to DM experienced a rapid and complete resolution of all clinical manifestations of intravenous immunoglobulin treatment was started. An 18 year old man had DM evolving from March 1999. The diagnosis of DM was made by the Bohan and Peter criteria: (a) symmetrical muscle weakness. Muscle power was gauged for eight proximal muscles (neck flexors, trapezius, deltoid, biceps, psoas, maximus and medius gluteus, and quadriceps) by a modification of the British Medical Research Council Grading system, resulting in a theoretical maximum score of 88 points. Muscle power of the patient was 73 points; (b) increased serum muscle enzymes—that is, creatine kinase (CK) 1700 U/l (normal 0.5–10), lactic acidosis (.values not available).

Myocardial changes on electrocardiography; (d) muscle damage on histological examination; and (e) characteristic dermatological manifestations—that is, heliotrope rash, periangual erythema, and poikiloderm.

Autoantibody screen was positive for anti-nuclear antibodies (ANA) with a value of 1/1000. Investigations, including pulmonary function tests, computed tomography scan of
clearly understood in PM/DM, though it may be related to vascularitis of small sized vessels, leading to ischaemia, haemorrhage, and perforation of the gastrointestinal wall. \(^{5,6}\) Moreover, the present case is original, as our patient with DM and life threatening digestive impairment received intravenous immunoglobulin treatment, which prevented gastrointestinal haemorrhage recurring and produced dramatic and rapid remission of swallowing disorders. Other authors have also considered a favourable outcome with intravenous immunoglobulin treatment in patients with systemic vasculitis—for example, Churg-Strauss vasculitis, microscopic polyangiitis, and lupus erythematosus. \(^{7,8}\) In this instance, a limitation was the concomitant continuation of steroids during the entire period of intravenous immunoglobulin treatment, making it difficult to be certain that the patient’s clinical improvement was only attributable to intravenous immunoglobulin treatment. However, the improvement of all gastrointestinal symptoms may reasonably be related to intravenous immunoglobulin treatments in our patient with DM because the gastrointestinal manifestations deteriorated persistently despite high doses of prednisone as a single treatment. The beneficial effect of the accompanying methotrexate therapy may also be excluded, as this later drug was started at the fifth month follow up of the patient.

Finally, our findings indicate that intravenous immunoglobulin should be considered the best treatment in both gastrointestinal-haemorrhage related to vascularitis and oesophageal dysfunction due to steroid refractory DM, such a treatment offering the advantages of efficacy and good tolerance. However, no definite conclusion can be drawn and further controlled trials with a large number of patients with PM/DM are required to establish optimal doses and effective management.

Sjögren’s syndrome: an unusual cause of Bell’s palsy

The most common form of facial paralysis is idiopathic—that is, Bell’s palsy. Sjögren’s syndrome (SS), a chronic inflammatory disorder characterised by lymphocytic infiltration of exocrine glands resulting in the so-called “sicca complex”, is a rare secondary cause of this self-limiting illness. Primary SS includes mostly peri-ocular, and to a lesser extent central autonomic neuropathy and central nervous system involvement. \(^{9}\) A patient with unilateral facial palsy, autoimmune hypothyroidism, and Sjögren’s syndrome is presented.

A 41 year old woman developed right sided facial numbness, described as “dentist anaesthesia for tooth extraction”. One day later she had a reduced sense of taste and right facial weakness. General physical examination was not remarkable. Neurological examination showed anisocoria, peripheral right sided facial paresis, reduced sense of taste on the right half of the tongue, and dysaesthesia in the face. There was no second segment of the right trigeminal nerve.

Although the erythrocyte sedimentation rate (ESR) was 30 mm/1st h, routine laboratory investigations were normal, including low IgA, IgG and IgM, negative rheumatoid factor and antinuclear factor/anti-nDNA antibodies/rheumatoid factor and RNP/SS-B/Sm antibodies. Rose-Bengal staining showed corneal punctate lesions (van Bjerstvedt score 6). Lower labial biopsy showed histopathological findings matching the diagnosis of SS with a
focus score of one lymphocyte focus for 4 mm² salivary gland tissue. Additionally, thyroid function tests showed a raised thyroid stimulating hormone (11 mU/L), low free thyroxine (13.0 pmol/L) with positive antithyroid microsomal antibodies and negative antithyroglobulin antibodies.

The clinical, serological, and histopathological manifestations fulfilled the European study group criteria for the diagnosis of SS. The patient was treated with artificial tears and thymine supplements that returned her thyroid function tests to normal.

Prevalence of neuropathy in patients with SS ranges from 10 to 50%. Polyneuropathy can be the first clinical manifestation of SS and may even precede sicca symptoms in 40% of patients. However, less frequently, cranial neuropathy can occur with a predisposition to involvement of the trigeminal nerve. The vasculitic damage to vaso nervorum documented by pathological studies is associated with a higher incidence of serum anti-SS-A (Ro) antibodies. The association of SS with autoimmune thyroid disease (AITD) is recognized. AITD and SS share similarities in the immunopathology in addition to their genetic linkage to the HLA-DR3/4 alleles. Only nine cases of facial nerve involvement associated with SS have been described previously.

This case illustrates how facial palsy disclosed the primary SS as an underlying systemic disorder. To our knowledge the combination Bell’s palsy as presenting feature in a patient with SS and hypothyroidism secondary to AITD has not been reported hitherto.

Table 2. α1 Antitrypsin alleles in ANCA* (anti-PR3* or anti-MPO*) positive patients

α1 Antitrypsin variant frequency is not associated with ANCA in southern Chinese

α1 Antitrypsin (α1AT) is a 52 kDa proteinase encoded by a gene locus Pi on chromosome segment 1q43-2.1. It is a natural inhibitor of proteinase 3 (PR3), a neutrophil granular protein and a major autoantigen of antineutrophil cytoplasmic antibody (ANCA). The function of α1AT is in turn restricted by myeloperoxidase (MPO), another autoantigen of ANCA. The interplay between the enzymes, inhibitors, and the autoantibodies is implicated in the dynamics of the vasculitic process, resulting in a whole spectrum of clinical conditions ranging from systemic granulomatous diseases to kidney limited glomerulonephritis. There have been reports of the correlation of specific α1AT alleles, notably Pi2, with ANCA. These were largely studies of white subjects, which may not necessarily be extrapolated to all populations.

α1AT variant frequencies may have predisposed to PR3-ANCA, but the same association may not exist for MPO-ANCA. In populations with a low prevalence of α1AT variant frequencies, the pattern of ANCA could differ from that in white subjects where such variants prevail. We set out therefore to establish the distribution of α1AT in patients with the two main forms of ANCA (anti-PR3 positive and anti-MPO positive). Blood samples of patients with vasculitis received at the immunology section of the Department of Pathology, Peking University Hospital, Beijing, Hong Kong, were tested for ANCA by indirect immunofluorescence, followed by enzyme linked immunosorbent assays (ELISA) for anti-PR3 and anti-MPO. α1AT phenotypes were determined by isoelectric focusing, the results of which were compared with those of healthy Chinese adults. A total of 137 samples from ANCA+ (either anti-MPO or anti-PR3 positive by ELISA) patients were evaluated. The prevalence of α1AT variant phenotypes of which were positive for anti-PR3 and 97 (62%) for anti-MPO by ELISA. All were Chinese patients with a clinical diagnosis of vasculitis. The female to male ratio was 0.76 (0.94 for anti-PR3 positive and 0.67 for anti-MPO positive patients). The mean age of the two groups was 52.4 and 59.4 years, respectively. A total of 103 (66%) were born in southern China, 50 (32%) were born in northern China (for example, M1 M2), and 4 (3%) were born in other countries and regions. A total of 103 (66%) were born in southern China, 50 (32%) were born in northern China (for example, M1 M2), and 4 (3%) were born in other countries and regions. associated diseases in southern Chinese among whom anti-MPO predominated.

A case of cholesterol embolism with ANCA treated with corticosteroid and cyclophosphamide

We report a case of a patient with cholesterol embolism who showed positive for both myeloperoxidase antineutrophil cytoplasmic antibody (MPO-ANCA) and proteinase 3 antineutrophil cytoplasmic antibody (PR3-ANCA) and who was treated with prednisolone (PSL) and cyclophosphamide.

A 50 year old man underwent cardiac catheterisation for back pain. The examination disclosed 90% stenosis of the right coronary artery and a saccular aneurysm in the thoracic aorta. The patient underwent percutaneous transluminal coronary angioplasty and the aneurysm was wrapped with an artificial blood vessel. Postoperatively, the patient had a fever, pleural effusion, abdominal pain, and increased white blood cell (WBC) count. C reactive protein (CRP), and serum creatine 3 antineutrophil cytoplasmic antibody positivity with the S allele. Nephrol Dial Transplant 1996;11:438-43.

Figure 1 Skin biopsy specimen showing cholesterol embolism in arterioles within subcutaneous tissues (haematoxylin and eosin, ×400).

h. Anaemia was noted with a red blood cell count of 2500×10^6/l, while the patient's WBC count was high at 12×10^9/l. His platelet count (304×10^9/l) was within the normal range. Biochemistry showed high levels of blood urea nitrogen (10.0 mmol/l of urea), creatinine (710 µmol/l), and CRP (11.3 mg/l). Complement components were within normal ranges. PR3-ANCA and MPO-ANCA were high at 82E and 29E, respectively. After admission to hospital, circulatory disturbance in his toes worsened. A diagnosis of ANCA associated vasculitis was made based on systemic inflammatory findings and high levels of WBC, CRP, PR3-ANCA, and MPO-ANCA. High dose steroid treatment was started. Biopsies of the right heel skin and thigh quadriceps showed cholesterol embolism (fig 1). However, PSL treatment was continued together with three courses of cyclophosphamide pulse treatment because of persistent fever and high ANCA values. The treatment reduced the fever and toe necrosis, and the ulcers improved. ANCA gradually decreased to normal. The PSL dosage was reduced to 15 mg/day and the patient was discharged.

Cholesterol embolism predominantly affects elderly men with a history of hypertension, atherosclerotic vascular diseases, and renal insufficiency at the time of diagnosis. At least 31% of patients had a preceding history of anticoagulant use or the antecedent performance of a vascular procedure affecting the arterial circulation. The presence of these cholesterol embolisms within the vascular lumen triggers a characteristic localised inflammatory and endothelial vascular reaction. The inflammatory changes resulting from cholesterol embolism may be responsible for many of the systemic manifestations such as fever, weight loss, myalgia, leucocytosis, eosinophilia, and a raised ESR. Thus cholesterol embolism is referred to as both vasculitis look-alikes and pseudovasculitis syndrome. The prognosis is poor, particularly in the presence of acute renal failure. Three ANCA positive cases of cholesterol embolism have been described. Peat and Matheson reported an ANCA positive patient with dyspnoea and haemoptysis after acute deterioration of renal function. Cyclophosphamide and PSL improved the symptoms, but cyclophosphamide was discontinued and the PSL dose was reduced because renal and skin biopsies showed cholesterol embolisms. Subsequently, the patient died of intractable cardiac failure.

Kaplan-Pavlovic et al reported two cases of renal failure with positive MPO-ANCA. The details are unknown for one patient. The other patient was treated with corticosteroid alone. This patient required haemodialysis and amputation of the toes. Although their treatment did not result in the improvement of vasculitis, the combination of PSL and cyclophosphamide was effective in our patient with ANCA.

This result suggests that active treatment with corticosteroid and cyclophosphamide should be considered in ANCA positive cases of cholesterol embolism.

Auranofin is an oral gold preparation used in the treatment of rheumatoid arthritis (RA). During treatment, proteinuria has been reported in approximately 3% of patients. In a few cases in which renal biopsies were performed, a membranous nephropathy was shown to have developed. Several antirheumatic agents have been reported to induce renal manifestations or drug induced lupus reactions, or both, in patients with RA. In these subjects a genetic predisposition for HLA has previously been reported to induce renal manifestations or drug induced lupus reactions, or both, in patients with RA. In these subjects a genetic predisposition for HLA has previously been suggested.

To determine whether similar genetic factors might be operative in auranofin induced nephropathy, we analysed the HLA-DRB1, DQA1, and DQB1 alleles using a polymerase chain reaction. Furthermore, we investigated if the renal side effects were associated with serological findings in accordance with systemic lupus erythematosus (SLE), thus indicating the development of a drug induced lupus reaction.

Six patients (three female, three male) who developed biopsy proven membranous nephropathy or significant proteinuria (>0.5 g/day) during treatment with auranofin are reported. All patients met the American College of Rheumatology criteria for RA. The median age before onset of auranofin treatment was 72 (52–83) years, 4/6 patients were rheumatoid factor positive and 2/5 patients were antinuclear antibody (ANA) positive. The median duration of auranofin treatment before the onset of proteinuria was 5 (4–10) months.

During auranofin treatment, two patients developed an increased ANA titre (1/200 and 1/1600) but no antibodies against anti-dsDNA, SSA/SSB, Sm, or RNP were detected. None of the patients developed an increased serum creatinine level. After withdrawal of auranofin, proteinuria decreased significantly or disappeared in all cases.

Table 1 presents the HLA alleles.

A high frequency of the alleles associated with SLE—namely, DRB1*0301 (DR3), DQA1*0501, and DQB1*0201, was recorded in the patients developing membranous nephropathy or proteinuria during auranofin treatment. Of these, DRB1*0301 and DQA1*0501 occurred in 4/6 of the patients, and 5/6 patients carried at least one of these alleles.

The importance of DR3 or DQA1*0501 in drug induced renal manifestations has previously been suggested in patients with penicillamine and sodium aurothiomolate induced renal side effects. Also, in accordance with these findings, the DQA1*0501 and DRB1*0301 alleles have been recorded in a high frequency in patients developing sulfasalazine induced nephritis.

In two cases the development of membranous nephropathy was accompanied by a simultaneous increase in the ANA titre, thus indicating development of a drug induced SLE reaction. However, both patients had previously presented some sign of an autoimmune reactivity pattern, which may confer a risk factor in the treatment with certain antirheumatic drugs in RA.

Simultaneous treatment with sulfasalazine had been given in two cases, but as the sulfasalazine treatment period was either limited, or lacked any time relation with the onset of proteinuria, it seems unlikely that the patients developed a drug reaction against sulfasalazine. Further arguments rejecting the possibility of a sulfasalazine induced drug reaction are the lack of anti-dsDNA antibodies and the rapid onset of proteinuria among the patients, thus contrasting with the findings reported in sulfasalazine induced SLE.

The mechanism for induction of membranous nephropathy during auranofin treatment is unknown. Interestingly, it has been suggested that gold can bind to and alter major histocompatibility complex-peptide complexes, thus giving a possible explanation of both beneficial effects as well as side effects during treatment. Another possibility is that auranofin may alter the cytokine pattern towards an SLE-like phenotype and thus facilitate the development of SLE associated manifestations in genetically susceptible subjects. In accordance with this hypothesis, auranofin or other gold preparations have been reported to inhibit the production of interleukin 1 (IL1), tumour necrosis factor α, and IL2. The effects on IL10, a cytokine reported to be increased in both patients with idiopathic SLE and their relatives as well as in patients developing sulfasalazine induced SLE-like reactions, is unknown, however.

In conclusion, the data suggest that SLE related HLA alleles, with special focus on DRB1*0301 and DQA1*0501, may predispose to development of renal side effects or drug induced lupus reactions during treatment with auranofin, as also previously recorded during treatment with other antirheumatic agents. Development of drug induced SLE, here reported for the first time, may occur during auranofin treatment.
