Calcium apatite crystals in synovial fluid rice bodies

J Li-Yu, G M Clayburne, M S Sieck, S E Walker, B H Athreya, R J DeHoratius, H R Schumacher Jr

Background: Rice bodies can occur in the joints in many rheumatic conditions, but they are most common in rheumatoid arthritis. They are generally believed to occur rarely in patients with osteoarthritis, but one study reported rice bodies with apatite crystals.

Objective: To report on a series of joint fluids with rice bodies containing apatite clumps and examine their clinical pictures.

Methods: All synovial fluid analysis reports for 10 years were reviewed for rice bodies and eight patients were reported on. A series of patients with a variety of diseases with synovial fluid rice bodies found to contain calcific material is described. All were examined by compensated polarised light and alizarin red stain, and four were examined by electron microscopy.

Results: The eight patients all had alizarin red S chunks embedded throughout the rice body. Transmission electron microscopy disclosed the presence of a matrix of collagen, fibrin, and amorphous materials containing typical apatite crystals. Clinical diagnoses, radiographic findings, and leucocyte counts varied, but six of the eight patients had had previous repeated corticosteroid injections into the joints.

Conclusion: Aggregates of apatites may be more common than previously recognised in rice bodies as they are not routinely sought. Whether they are a result of joint damage or depot steroid injections and whether that might contribute to further joint injury now needs to be investigated.

RESULTS
Table 1 summarises the clinical characteristics of the eight patients. Six patients were male and two female, with a median age of 53 years (range 5–75 years). Diagnoses included RA (n=5), camptodactyly arthritis syndrome (n=1), OA (n=1), and septic bursitis (n=1). The most commonly involved joint was the knee, which was affected in four cases, the shoulder joint in two cases, and subacromial bursa and proximal interphalangeal joint in one case each. Six patients had a history of multiple intra-articular steroid injections of the affected joint because of refractory pain and swelling. Radiographic findings available for some of the patients were mostly compatible with changes of OA (table 1).

In these fluids with apatite containing rice bodies, synovial fluid leucocyte counts ranged from 0.05 to 45.8×10⁶ cells/l with a mean count of 11.0×10⁶ cells/l. Patients 4 and 5 had undergone arthroscopic lavage of their knees from which the synovial fluids with the rice bodies were obtained.

All rice bodies in these eight specimens contained shiny irregular 1–15 µm chunks that stained strongly with alizarin red S and were thus highly suggestive of clumps of apatite crystals (fig 1). Calcium stains such as alizarin red S, have been used to screen for hydroxyapatite and other calcium containing crystals in synovial effusions and joint tissues. Although the method is sensitive, it is non-specific for calcium phosphate, and may give false positive results with CPPD, calcium oxalate, and other calcium containing compounds and, occasionally, with other metals. Smaller amounts of alizarin red S chunks were seen outside the rice bodies in three cases; these were not analysed further. Routine light microscopy in two of the cases showed additionally, the presence of rod-shaped crystals which were positively birefringent under polarised light and thus characteristic of CPPD.

Abbreviations: CPPD, calcium pyrophosphate dihydrate; OA, osteoarthritis; RA, rheumatoid arthritis; SF, synovial fluid

EXTENDED REPORT
Electron microscopic studies of the rice bodies performed in patients 1–4 all confirmed the presence of typical tiny apatite-like crystals of 100–250 Å length (figs 2A and B). Some of the crystals were in finely granular electron dense material in vacuoles of macrophages; others were enfolded by cell processes as if about to be phagocytosed (figs 2 and 3). The rice bodies were composed of coarse and fine strands of fibrin with typical striations. Some areas exhibited collagen fibres embedded in amorphous material. There were, likewise, occasional viable appearing or degenerated cells scattered within the fibrin (fig 4). Cells were mononuclear, mostly macrophages, and occurred on the surface or within the fibrinous network. Features suggestive of CPPD crystals (fig 3) were seen in two patients by electron microscopy.

One patient (No 1) had both electron microscopy and elemental analysis performed on the electron microscopic specimen as noted above. This patient’s crystals had calcium-phosphorus (Ca:P) molar ratios of 1:4:1 and 1:1 on electron probe elemental analysis, consistent with some being carbonate substituted apatite and others CPPD. X-ray diffraction studies of the crystals in this patient confirmed the presence of both calcium hydroxyapatite and CPPD crystals.

Patient No 4 merits further description. This 5 year old Hungarian boy was brought to a paediatric rheumatologist for a second opinion because of swelling of his joints and flexion contractures of fingers since infancy. His knees began to swell at age 18 months. There was flexion deformity of the fifth fingers, with some nodules along the flexor tendons of the fingers. A trial of indometacin was apparently given, with no benefit noted. His mother recalled that injections of steroids had been given, although details were not clear.

Pertinent joint examination showed his left thumb to be fixed in a flexed position. The right sternoclavicular joint was slightly swollen, with some degree of synovial thickening of
the left shoulder. The synovium at the right elbow was thick-ened, with limitation in extension. Both wrist joints had moderate swelling with full range of motion. Both knees had consider-able swelling, particularly at the left knee, with proliferative synovium and very little fluid. Flexion was limited on both sides, especially the left which was unable to pass 90–100° flexion. Both ankles had synovial hypertrophy with limitation of extension. Blood tests, including complete blood counts, liver, renal, and thyroid function tests, and angiotensin converting enzyme levels, were all normal. Erythrocyte sedimentation rate was only 4 mm/1st h. Antinuclear antibody was negative; immunoglobulin levels and rheuma-toid factor were both negative.

Radiographs showed no destructive changes in the knees; there was soft tissue swelling in his ankles. There was a little beaking of the dorsal part of the talus. His wrists showed soft tissue swelling. Both hips had cystic changes in the acetabulum and in the femoral neck.

Synovial fluid aspiration of his left knee disclosed rice bod-ies on gross inspection, with a non-inflammatory count of 92×10⁶ leucocytes/l. Synovial biopsy showed fibrin over a thin layer of synovial lining cells, with other areas having no lining cells at all. The deeper synovium contained giant cells, some fibrin, and diffuse fibrotic reaction. These findings were felt to be characteristic of the camptodactyly arthritis syndrome.

He eventually underwent left knee synovectomy. Pertinent family history disclosed an uncle who had flexion contractures of toes from birth and was operated on at age 20. Two older sib-lings had died from an apparent “inborn error of metabo-lism”; one died at 8½ months old and the other at 3 months.

**DISCUSSION**

Many studies have reported the presence of rice bodies in joint fluid specimens from patients with inflammatory diseases, and especially in RA. Bucki *et al* first detected rice bodies in joint fluid specimens of four patients with non-inflammatory joint disease and identified apatite deposits in these.¹⁰ We like-wise found evidence of apatite crystal clumps in rice bodies but, as noted, also found these in a variety of cases in addition to OA.

The origin of rice bodies is almost certainly from the synovium, and their clinical significance has always been obscure. It has most frequently been proposed that microvas-cular disease within the rheumatoid synovial tissue leads to synovial microinfarcts. Subsequent sloughing of the infarcted tissue into the joint cavity with the surface then covered by fibrin layers may lead to the classical appearance of rice bodies.¹⁴ ¹⁵ Others more generally regarded rice bodies as end products of synovial inflammation, proliferation, and
degeneration. One fascinating aspect is the persistence of rice bodies in the joint as seen in our patient No 3 on repeated arthrocenteses. In general, there is a paucity of inflammatory cells noted within the rice bodies as also seen in our cases.

Factors involved in development of apatite in these rice bodies need consideration. Repeated local steroid injections appear to be a factor worth investigating as this was reported in six and possibly in a seventh case. Local steroids have previously been reported to cause apatite deposits. OA is another known cause for apatite presence in SF and was reported by Bucki et al. Apatite crystals are also common in SF of patients with OA who have no rice bodies. Although only one of our patients had OA as the primary diagnosis, five had changes of OA on x-ray examination.

Whether apatite and other basic calcium phosphate crystals contribute to joint damage in the arthritides or merely represent an epiphenomenon remains unknown. Apatite crystal clumps or CPPD maybe more common in rice bodies than previously recognised. These occur not only in OA but also in some inflammatory arthritis. Future studies need to consider these crystals as either factors in formation of rice bodies or contributors to the generally more destructive arthritis seen in patients with rice bodies. In conclusion, apatite deposits are a previously underrecognised feature of rice bodies. Might apatite just have been missed in others with RA because it was not considered?

REFERENCES
