Long term treatment of psoriatic arthritis with infliximab

We read with great interest the article by Feletar et al.\(^1\) We were surprised by their findings of only a modest response to infliximab treatment in patients with treatment refractory psoriatic arthritis (PsA), as this seems to be in contrast with our observations.

Since 2001 nine patients with refractory PsA according to American College of Rheumatology criteria have been treated with infliximab at our division. All patients had active joint disease with a tender joint count (TJC) and a swollen joint count (SJC) of at least 6, with the exception of one patient (patient 3), whose cervical spine was affected. Quantitative assessment of skin involvement was not available. Table 1 shows further demographic data.

Seven patients received infliximab for more than 52 weeks, and five of those for more than 78 weeks. Clinical assessment, including TJC and SJC, performed by experienced rheumatologists, and laboratory tests (haematology, biochemistry, antinuclear antibodies (ANA), including subsets) was made routinely at each visit (fig 1). During the treatment period toxicity occurred on three occasions, including one labial herpes infection (patient 4), one leucopenia of 2.6×10\(^9\)/l (patient 3), which led to the discontinuation of methotrexate, and one allergic reaction (patient 9). Patient 9 had to stop infliximab treatment permanently despite an excellent clinical response, whereas the other two patients received infliximab again after the adverse events resolved. Six of the nine patients became positive for ANA—titre >1/80 on at least two successive visits. No serum conversion of ANA subsets occurred and no lupus-like symptoms were seen.

Eight of the nine patients showed rapid improvement and a clinical response. Only 1 patient (patient 8) was unresponsive to the treatment regimen, which was stopped. At 52 weeks five patients met the PsA response criteria,\(^2\) four patients were in complete remission (patients 1, 3, 5, 6) of joint tenderness and swelling, one patient (patient

Figure 1 Changes in (A) TJC, (B) SJC, and (C) C reactive protein levels (normal value <9 mg/l) of each patient during the respective treatment period. Infliximab treatment was stopped because of insufficient response (1) or allergic reaction (2). Disease exacerbation occurred when infliximab was stopped owing to herpes labialis infection (3). Shortening of the infliximab application interval to 4 weeks (4).
2) had an incomplete response. Patient 4 stopped infliximab treatment in week 49 for 10 weeks because of a labial herpes infection that was treated with acyclovir. Thereafter tumour necrosis factor blocking therapy was successfully restarted.

At 78 weeks 4/5 patients (patients 1, 3, 4, 5) were in complete remission. One patient (patient 2) who had an incomplete response with a 6 weeks’ treatment interval showed complete remission after the interval was shortened to 4 weeks. Patient 1 who received his first infliximab dose at our division 16 weeks ago had been responding so well to the treatment that we stopped giving infliximab after his 16th infusion at the end of week 120. Because of disease exacerbation, treatment had to be restarted 26 weeks later and within a few days (data not shown) the patient regained complete remission.

These data, although only retrospectively obtained, suggest that infliximab is a valuable therapeutic tool for treating refractory PA. So far, permanent discontinuation of treatment owing to toxicity or inefficiency has only been necessary for one of the nine patients.

One possible reason for the different outcome in the effect of infliximab on PA in our patients and those of Feletar et al might be the severity of the joint disease in Feletar’s patients. Fifteen out of 16 of their patients had mutilating arthritis, whereas this form of joint destruction was not present in our group. To clarify this possibility, further studies with larger groups and well defined joint disease are necessary.

Author’s reply
Yazdani-Biuki et al were surprised that our data on 16 patients with arthritis treated with infliximab demonstrated only a modest response. They contrast our data with data from nine patients with psoriatic arthritis (PsA) treated with infliximab in their centre. Although they mention nine patients, only seven were treated for more than 52 weeks. They claim that eight of the nine patients demonstrated rapid clinical response, but provided information on only five patients who demonstrated a PsA American College of Rheumatology response, four of whom are said to be in complete remission. It is not clear whether the other patients discontinued the drug, in which case their withdrawal rate would be 22%.

This is in contrast with the results of our study, which demonstrated a high toxicity rate, and high level of discontinuation (6/16 or 38%). We had previously suggested that the difference between our study and others might reflect the severity of our patient group. The group treated by Yazdani-Biuki et al was demographically somewhat different from our group. There were more men in our study (12/16 or 4/5), they were older (48 vs 41), and had longer disease duration (14 vs 10.5). However, the same average number of disease modifying antirheumatic drugs had been used in the two groups. Yazdani-Biuki et al did not provide information on damage in their patients. Our group included five patients with arthritis mutilans; however, all these patients had evidence of inflammatory arthritis. The other five patients may have had evidence of damage but did not demonstrate arthritis mutilans. Because we have previously shown that the presence of damage predisposes not only to progression of damage but also to early mortality in this patient group, we felt it was important to give these patients better treatment.

We agree with Yazdani-Biuki et al that the difference between the results of our two studies may be related to the difference in disease severity between the two groups. However, the number of patients is too small to draw valid conclusions. It is important to gain more experience with anti-tumour necrosis factor agents both in randomised clinical trials and clinical observational studies, including a wide range of patients with PsA, so that the true level of response and toxicity can be identified.

Immunohistochemistry of normal synovium
A recent paper published in the Annals of the Rheumatic Diseases by Singh et al claimed to be the first report of immunohistochemical features of knee synovium in such a large number of healthy normal subjects. This statement is incorrect and I am surprised that the authors of this paper appear to be unaware of our paper published more than 12 months previously in the same journal.

We studied 20 normal patients attending a sports medicine clinic with unexplained knee pain who had no evidence of any form of arthritis on history, examination, and laboratory tests and had normal x ray findings and normal knee arthroscopy. Although Singh et al may argue about the source of our “normal” subjects, it is noted that several of their subjects were not entirely normal.

We are, at least, in a better position to state that our patients were as close as possible to normal than the study of Singh et al, who relied on normal x ray examinations to exclude joint pathology (including early osteoarthritis) and included patients with either a positive rheumatoid factor or a raised erythrocyte sedimentation rate (ESR), neither of which was included in our patient group.

In the two studies the patient group and the variables measured in the synovial membrane were similar, and the conclusions of both studies were also similar. Like the study of Singh et al, we found wide variability in the architecture of the normal synovial membrane, particularly in relation to the thickness of the lining layer and the subintimal cell infiltrate, but we also measured cytokine production, cell adhesion molecule expression, and mediators of osteoarticular degradation, which were not included in the study of Singh et al. We did find evidence of B cells and occasional plasma cells in the normal synovial membranes, unlike Singh et al, but these cell populations were quite sparse.

It is, however, very surprising that neither the journal reviewers nor the authors of this paper appeared to be aware of a similar paper published in the same journal before this paper was accepted for publication, and we do dispute the statement of Singh et al that they have published the “first report of immunohistochemical features of knee synovium in such a large number of healthy normal subjects”.

Authors’ reply

We thank Dr Smith for alerting readers and us to the existence of his excellent paper that came out after our study was done and during the preparation of our manuscript. Our study described asymptomatic subjects, a somewhat different group from that in Dr Smith’s study—namely, patients with unexplained knee pain with clinically and arthroscopically normal knee joints. It is fascinating that in his study arthroscopy could not detect moderate inflammation seen in some cases. Thus, some synovitis can be present even when examinations and gross arthroscopy are normal. Future studies of patients like ours and those of Smith et al. would benefit from longer follow up. What was the final cause of the knee pain that led to the need for arthroscopy? Will the cellular pattern be consistent, resolving, or progressive in some patients? Do the infiltrates seen in some “normal subjects” have any prognostic significance?

It appears that our two studies1 2 with many similar findings reinforce the point, also noted before by Lindblad and Hedfors,3 that there may be more variability in synovial histology and inflammation than meets the eye.

2 Smith MD, Boon E, Wessendorf P, Van Der Linden S. Quantitative synovial histology in rheumatoid arthritis: an essential concern noted above. For example, although these are less important than the key findings of the COBRA study, and clinical benefit over two years of low dose prednisolone for rheumatoid arthritis (RA). A number of important aspects of the trial have been dealt with well: the sample size is adequate; appropriate attention has been paid to confounders; two separate and independent readers scored the radiographs; we have since been shown to increase over time.1 3

Low dose prednisolone for treatment of RA

We read with interest the report of the WOSERACT trial3 that compared the addition of 7 mg daily prednisolone or placebo to sulfasalazine in early rheumatoid arthritis (RA). A number of important aspects of the trial have been dealt with well: the sample size is adequate; appropriate attention has been paid to confounders; two separate and independent readers scored the radiographs; the 2 year trial was of adequate length; and independent readers scored the radiographs; the 2 year trial was of adequate length; and the test of the difference between medians at baseline and end point is not the same as the median change.

Secondly, most trials choose two readers who read either with sequence known or unknown (the jury is still out on which is the preferred method), and report the mean of these two readings. This report has two readers, each of whom uses a different one of these options, and this makes it impossible to pool the results. Also, even with sequence unknown, films should be read as sets (all films belonging to a patient assessed simultaneously, not totally at random. Reading totally at random strongly decreases the signal to noise ratio.1 Which method did the “random” reader apply exactly?

A third concern is with the analysis, although this may only be a question of the way in which the data are presented. Although the authors state that the main outcome measure is the change in radiographic damage, they only report medians and ranges of the absolute scores in the groups. From our reading of the report, we fear the analysis has (statistically) compared the distributions of these absolute scores rather than their changes.

This is an important study, and has the potential to add valuable information to our understanding of the best way to treat RA, but in its present form the radiographic results are more likely to cloud the issues than clarify them. We suggest that the radiographs are made available to be re-read by new, experienced readers, with either the sequence known or unknown to both.

There are other difficulties with the study, although these are less important than the essential concerns noted above. For example, we are baffled by the statement in the introduction that the COBRA combination ‘showed radiological advantage over sulfasalazine alone but the study was not powered to detect differences in x ray change’. In fact, the differences in xray change were among the key findings of the COBRA study, and have since been shown to increase over time.1 So the study was not only adequately powered but also showed an unexpectedly large effect.

The authors diminish the value of the report by inappropriate interpretation of their secondary data, especially on the adverse effects. In their discussion they comment: “While observed toxicity from corticosteroids in patients with early rheumatoid arthritis: long-term osteoporosis could be reduced by active assessment and prompt intervention, there is no room for complacency”. However, in their results section they report that, “Low dose aspirin and treatment for ischaemic heart disease remained similar, whereas the use of antihypertensive agents increased in both groups, as did prescription of lipid lowering agents. The use of any treatment for osteoporosis in those who read either with sequence known or unknown (the jury is still out on which is the preferred method), and report the mean of these two readings. This report has two readers, each of whom uses a different one of these options, and this makes it impossible to pool the results. Also, even with sequence unknown, films should be read as sets (all films belonging to a patient assessed simultaneously, not totally at random. Authors’ reply

We agree with John Kirwan and Maarten Boers that the assessment of radiographic damage in the WOSERACT study is of importance. The method of reading radiographs has evolved since this study was planned in 1995. Because we consider that “the jury is out”, on the optimal way to read radiographs in studies the films were read at (a) at random by one reader and (b) in sequence by the other reader, and the same conclusion was reached. This strengthens rather than weakens the case for a true result.

The study of Paulus et al., in which there was no beneficial effect on radiographic outcome in 197 patients with rheumatoid arthritis (RA), supports the WOSERACT study findings. It was unfortunate that in the Arthritis and Rheumatism Council (ARC) low dose corticosteroid-study the two groups were not well matched at the outset, making interpretation of the true effect of prednisolone at 2 years and of the subsequent report difficult.1 The COBRA study used a high initial corticosteroid dose and the effects contributing to prompt disease control were multifactorial. It is similarly not possible to extrapolate from the study of van Everdingen et al.2 because they used a protocol of steroid without initial disease modifying antirheumatic drug, which is not a practice supported by current guidelines on RA management.

There was considerable discussion among the WOSERACT investigators about the approach to glucocorticoid side effects. It was decided that management of these would be the responsibility of the individual consultant, who remained unaware of the treatment assignment. For this reason there is likely to be a great deal of background noise. This issue was not a primary end point of our study but information is available from other studies.3 We do agree that the blunting of sulphasalazine toxicity in the active group is of interest, although it would be inappropriate to advocate the use of prednisolone for this reason alone.

At a time when multiple treatments are increasingly used in early RA it is vital to be certain what contribution, if any, oral corticosteroids might make. The fact that both the ARC study and ours showed no sustained clinical benefit, makes x ray interpretation all the more important.

Thus we suggest that with John Kirwan and Marten Boers an approach is made to the ARC (the original sponsors of the 1995 study), or to EULAR, for sufficient funding to allow independent readers and statisticians to evaluate all appropriate datasets. This would allow films from relevant studies to be copied and made available as a central repository for future study. The films from the study of Rau et al4 would also be useful for this initiative.
