Expression of matrix metalloproteinases in patients with Wegener’s granulomatosis

V Bjerkeli, B Halvorsen, J K Damás, I Nordøy, A Yndestad, P Aukrust, S S Frøland

Background: Enhanced activity of matrix metalloproteinases (MMPs) has been reported to have a pathogenic role in several diseases such as cancer and cardiovascular disorders, and seems also to play a part in certain autoimmune diseases.

Objective: To examine whether enhanced MMP activity may also have a role in the pathogenesis of Wegener’s granulomatosis (WG).

Methods: In a study group of 15 patients with WG and 15 controls, plasma levels and gene expression were measured in freshly isolated peripheral blood mononuclear cells (PBMCs) of several MMPs and their endogenous inhibitors (that is, tissue inhibitors of metalloproteinases (TIMPs)) by enzyme immunoassays and RNase protection assay, respectively.

Results: Whereas patients with WG in remission had enhanced gene expression of several MMPs and TIMPs in PBMCs, those with active disease had a selective up regulation of MMP-2 and MMP-8 compared with healthy controls, and a down regulation of TIMP-1 and TIMP-3 compared with other patients with WG. Moreover, plasma levels of TIMP-1 and MMP-8 correlated significantly with C reactive protein levels, further supporting an association between activation of the MMP/TIMP system and disease activity in WG.

Finally, these changes in MMP/TIMP expression in WG were accompanied by increased total MMP activity in PBMC supernatants, particularly in those with active disease, suggesting a matrix degrading net effect.

Conclusion: These findings suggest that disturbed MMP and TIMP activity has a role in the pathogenesis of WG.

Wegener’s granulomatosis (WG) is a necrotising vasculitis of small and medium sized vessels characterised by chronic granulomatous inflammation of the upper and lower respiratory tract, often also affecting other organs, particularly the kidneys. The pathogenesis of WG has not been fully clarified, but seems to involve enhanced leucocyte and endothelial cell activation as well as increased oxidative stress. Moreover, patients with WG are characterised by raised levels of inflammatory cytokines, particularly Th1 related cytokines (for example, interferon γ and interleukin 12) and tumour necrosis factor α, possibly promoting inflammation and tissue destruction.

Matrix metalloproteinases (MMPs) are a family of endopeptidases containing zinc with common functional domains and mechanisms of action, discovered because of their ability to degrade extracellular matrix (ECM) components. Although these enzymes have a key role in many physiological processes (for example, embryonic development, angiogenesis, and tissue homeostasis and remodeling), a dysbalance between MMPs and their endogenous inhibitors (that is, tissue inhibitors of metalloproteinases (TIMPs)) may be harmful. Thus, increased MMP activity has been reported to have a pathogenic role in cancer and cardiovascular disorders as well as in certain autoimmune diseases—for example, systemic lupus erythematosus and rheumatoid arthritis.

The immune mediated tissue damage characterising WG could potentially also involve MMP activation. At present, however, there are no data on the involvement of MMPs or TIMPs in this disorder. To elucidate this issue we examined MMP and TIMP levels in WG by different experimental approaches, trying to relate their concentrations to disease activity.

Abbreviations: BVAS, Birmingham Vasculitis Activity Score; CRP, C reactive protein; ECM, extracellular matrix; EIA, enzyme immunoassay; ESR, erythrocyte sedimentation rate; MMP, matrix metalloproteinase; PBMC, peripheral blood mononuclear cell; RPA, RNase protection assay; TIMP, tissue inhibitor of matrix metalloproteinase; WG, Wegener’s granulomatosis
Blood sampling protocol
Peripheral venous blood was drawn into pyrogen-free tubes without additives (serum) or with EDTA as anticoagulant (plasma). The tubes were immediately immersed in melting ice and centrifuged (1500 g for 10 minutes) within 20 minutes (plasma) or allowed to clot before centrifugation (serum). All samples were stored at −280°C and thawed only once.

Isolation and culturing of cells
Peripheral blood mononuclear cells (PBMCs) were obtained from heparinised blood by Isopaque-Ficoll (Lymphoprep, Nycomed Pharma, Oslo, Norway) gradient centrifugation within 45 minutes. For mRNA analyses (see below), cell pellets were stored in liquid nitrogen until used for RNA extraction. For analyses of MMP activity, PBMCs (2 × 10⁶/ml, 1 ml/well) were incubated in flat bottomed, 24 well microtitre plates (Costar, Cambridge, MA) with serum-free medium (X-vivo; Bio-Whittaker, Walkersville, MD). After different times, cell-free supernatants were removed and stored at −80°C.

RNase protection assay (RPA)
Total RNA was extracted from PBMCs using RNeasy columns (Qiagen, Hilden, Germany) and stored in RNA storage solution (Ambion, Austin, TX) at −80°C. RPA was performed as previously described using the hMMP-2 multiprobe (Pharmingen, San Diego, CA). The mRNA signal was normalised to the signal from the housekeeping gene ribosomal protein L32 (rpL32).

Zymography
Gelatinase activity was detected in PBMC supernatant after incubation for 18 hours, as previously described. Briefly, 46 μg of protein was incubated with a sample buffer containing 2% sodium dodecyl sulphate. Human pro-MMP-9 and active MMP-9 (Oncogene, Cambridge, MA) were run in a separate lane to ensure identification of MMP activity. Gels were scanned by Kodak 440 CF imaging station (Vector, Burlingame, CA), and the software Total Laboratory (Phoretix, Newcastle, UK) was used for quantification.

Total MMP activity
Total MMP activity in PBMC supernatants was measured by a fluorogenic peptide substrate (R&D systems, Minneapolis, MN; cat no: ES001) using the protocol recommended by the manufacturer. Briefly, the MMP substrate was diluted in TCN buffer (50 mM Tris HCl, 150 mM NaCl, 10 mM CaCl₂; pH 7.5) and added to the supernatants (preactivated by aminophenylmercuric acetate (Sigma, St Louis, MO) for 1 hour) before incubation at 37°C. After 30 minutes the total MMP activity was determined on a fluorimeter (FLX 800 Microplate Fluorescence Reader; Bio-Tek Instruments, Winooski, VT).

disease and healthy controls.

Enzyme immunoassays (EIAs)
Plasma concentrations of MMP-3, MMP-8, and TIMP-1 were
quantified by EIAs (R&D System). MMP-2 levels were analysed by EIA (Amersham Biosciences, Buckinghamshire,
UK). The intra- and interassay coefficients of variation were
<10% for all EIAs.

Statistical analysis
Statistical comparisons between patients with WG and
healthy controls and between different groups of patients
with WG were performed using the Mann-Whitney rank sum
test. Relationships between variables were tested using
Spearman's rank correlation test. Values of $p$ were two-sided
and were considered significant when $<0.05$.

RESULTS
Gene expression levels of MMPs and TIMPs
We first analysed the gene expression of several MMPs and
TIMPs in PBMCs from patients with WG (n = 15) and
healthy controls (n = 15). Figure 1 shows that while several
MMPs (that is, MMP-1, MMP-2, MMP-3, MMP-12, and
MMP-14) were moderately up regulated in patients with WG
in remission, those with active disease showed a different
pattern, with a selective and marked up regulation of MMP-2
(p < 0.01) and MMP-8 (p < 0.01) compared with gene expres-

Figure 4 Plasma levels of MMP-3 (A), MMP-8 (B), and TIMP-1 (C) in 15
patients with WG classified as having active disease (n = 7) or being in
remission (n = 8) according to the BVAS, serum levels of CRP, and ESR
(see table 1). Data are given as mean (SEM). $*p < 0.01$ and $**p < 0.005$
versus patients in remission.

Plasma levels of MMPs and TIMPs
To further examine the MMP/TIMP system in WG, we
examined plasma levels of MMP-2, MMP-3, MMP-8, and
TIMP-1, all shown to be dysregulated in WG at the mRNA
levels (see above), in 15 patients with WG and 15 healthy
controls. Figure 3 shows that patients with WG had
enhanced plasma levels of MMP-2, MMP-3, and TIMP-1
compared with healthy controls. Moreover, when the
patients with WG were classified as having active disease
(n = 7) or being in remission (n = 8) (table 1), we found that
those with active disease had raised plasma levels of MMP-3,
MMP-8, and TIMP-1 compared with the other patients with
WG, although the difference for MMP-8 (p = 0.053) did not
reach significance (fig 4). Moreover, plasma levels of TIMP-1
and MMP-8, but not MMP-2 and MMP-3, correlated
significantly with CRP levels in the patient group as a whole
(fig 5).

MMP activity
To examine if this altered MMP and TIMP expression
resulted in any changes in MMP activity, we first measured
total MMP activity in PBMC supernatants from nine patients
with WG (five in remission and four with active disease)
and eight healthy controls. Figure 6 shows that the substrate used
in this assay can be cleaved by MMP-1, MMP-2, MMP-7,
MMP-8, MMP-9, MMP-12, and MMP-13. The changes in
MMP and TIMP expression in WG were accompanied by a
significant increase in total MMP activity, particularly in
DISCUSSION

In this study we report that patients with WG are characterised by marked alterations in gene expression of several MMPs and TIMPs in PBMCs. Whereas patients with WG in remission had moderately enhanced expression of several MMPs and TIMPs, those with active disease had a selective and marked up regulation of MMP-2 and MMP-8 compared with healthy controls, and a down regulation of TIMP-1 and TIMP-3 compared with other patients with WG. Finally, these changes in MMP/TIMP expression in WG were accompanied by increased total MMP activity in PBMC supernatants, particularly in those with active disease, indicating a matrix degrading net effect. Although we cannot exclude the possibility that some of these findings may reflect the use of immunosuppressive drugs in the patient group, our results suggest a role for disturbed MMP/TIMP activity in the pathogenesis of WG.

MMPs are a pivotal family of zinc enzymes responsible for degradation of the ECM components. In this study we show that PBMCs from patients with WG have markedly enhanced expression of several MMPs with the potential to induce degradation of tissue components such as collagen, fibronectin, and various proteoglycans. Notably, patients with WG with active disease were characterised by a selective and marked up regulation of MMP-2 and MMP-8 and, as for MMP-8, such an association with disease activity was also found for plasma levels. Among collagenases, MMP-8 most effectively hydrolyses the native type I and II collagens. It has been suggested that this MMP has a pathogenic role in disorders such as chronic bronchiectasis, cystic fibrosis, and rheumatoid arthritis, and although we have no data on MMP-8 enzymatic activity, our results suggest that this MMP also may be a part in the pathogenesis of WG.

The activity of MMPs is regulated by several factors such as the levels of their naturally occurring inhibitors (for example, TIMPs). Although the increase in MMP levels was accompanied by enhanced expression of TIMP-1 and TIMP-3 in patients with WG in remission, this was not found in those with active disease. Such an imbalance between MMPs and their endogenous inhibitors was also indicated at the functional level, showing enhanced total MMP activity in patients with WG, particularly in those with active disease. While patients with active disease showed no increase in TIMP-1 gene expression in PBMCs, these patients had raised plasma levels of this inhibitor. The reasons for these apparently discrepant results are at present not clear but several possibilities exist. Firstly, plasma levels of TIMP-1 will not only reflect the production in PBMCs but also other cells, such as endothelial cells and tissue macrophages, may be of even more importance. Moreover, while the TIMP-1 level in PBMCs reflects the actual TIMP-1 expression in this cell population, plasma levels of TIMP-1 may also be regarded as a measure of the activity in the TIMP/MMP system.

Several studies have shown potent induction of MMP expression by inflammatory cytokines such as tumour necrosis factor, interleukin 12, and chemokines. Because a number of reports have shown increased levels of such inflammatory cytokines in WG, it is not inconceivable that cytokine-induced MMP activity may also be operating in this disorder. Whatever the mechanisms, this disturbed MMP/TIMP expression in WG with net ECM degrading effects may have several pathogenic consequences. Thus, studies in animal models suggest that enhanced MMP activity may promote tissue destruction, remodelling, and fibrosis in the lungs. Moreover, recent studies in rat models suggest the involvement of MMP-2 and MMP-14 in the pathogenesis of crescentic glomerulonephritis. Furthermore, although the role of MMPs in various nasal...
disorders is largely unclear, enhanced MMP activity seems to play a part in the pathogenesis of nasal polyps and allergic rhinitis,25–26 and even more importantly with relevance to WG, several MMPs (for example, MMP-1, MMP-3, and MMP-8) have been shown to promote degradation of type II collagen and proteoglycan in nasal cartilages.27–29 Finally, while inflammatory cytokines are potent inducers of MMPs, enhanced MMP activity may itself promote inflammation and granuloma formation, representing a possible link between tissue destruction/remodelling and inflammation in various disorders.30

Unbalanced MMP activity has been demonstrated in several disorders, such as arthritis, malignancies, and arteriosclerosis, and although not specific for WG, our demonstration of a correlation between MMP/TIMP levels and disease activity, as assessed by both clinical and laboratory criteria, suggests that such a pathogenic link may also be operating in WG. Although these findings will have to be confirmed also at the tissue level, particularly in target organs, our results suggest that WG may be added to this list of disorders characterised by dysregulated MMP/TIMP levels, possibly representing a new target for treatment in this disorder.
