Peripheral ulcerative keratitis in rheumatoid arthritis: successful use of intravenous cyclophosphamide and comparison of clinical and serological characteristics

A R Clewes, J K Dawson, S Kaye, R C Bucknall

Peripheral ulcerative keratitis (PUK) is a devastating complication of rheumatoid arthritis (RA) that can lead to rapid corneal destruction (corneal melt) and perforation with loss of vision (fig 1). It is well reported to herald systemic vasculitis and carries a high mortality rate if not aggressively treated. There is a paucity of information concerning the clinical and serological characteristics of these patients and no clear consensus about treatment.

We report the successful management of seven such patients with the use of intravenous cyclophosphamide and compare the serological and clinical characteristics with a comparative group of 150 rheumatoid patients without associated PUK, who attended an outpatient clinic.

CASE REPORTS

All patients received systemic immunosuppressive treatment with intravenous cyclophosphamide and the dose was dependent on age, weight, renal function, and clinical response. All received some form of adjunctive ocular treatment including cyanoacrylate glue, bandage contact lenses, punctual occlusion, and corneal transplants. Two patients also received intravenous corticosteroid treatment with 1 g methylprednisolone (table 1).

Student’s $t$ test was used to compare the melt and comparative groups, the Mann-Whitney U test to compare quantitative data, and a $\chi^2$ squared test with Fisher’s exact test to compare frequencies. No difference in duration of disease, presence of rheumatoid nodules, Sjögren’s syndrome, or seropositivity for rheumatoid factor was found between the groups. Disease activity did not correlate with ocular disease and there was no active synovitis at presentation. The melt group were older (median age 71.9 v 58.9 years, $p = 0.013$) and were more inclined to be antinuclear antibody (ANA) positive ($p = 0.03$). Serum albumin levels were statistically lower (36.7 g/l v 40.83 g/l, $p = 0.012$) and immunoglobulin levels polyclonally increased (IgA 3.62 v 2.80 g/l, $p = 0.055$; IgG 3.93 v 1.42 g/l, $p = 0.001$; IgM 16.74 v 10.97 g/l, $p = 0.005$). A previous history of scleritis seemed to correlate with increased risk of PUK ($p = 0.002$), but the presence of sicca disease did not reach significance ($p = 0.165$).

DISCUSSION

No correlation between articular activity and PUK was found, but there was a statistically significant association with the presence of ANA, raised immunoglobulins, and reduced albumin concentrations when compared with the comparative group. This may represent increased subclinical disease activity. The pathogenic mechanisms behind PUK are still unclear but whatever the mechanisms, the important issue is that this condition needs aggressive treatment with immunosuppression. Foster et al compared the outcome of 34 patients with rheumatoid associated necrotising scleritis and PUK, half of whom received systemic immunosuppressive treatment and half non-immunosuppressive topical conventional treatment. In those not receiving immunosuppression, vasculitis developed in more than 50% of cases with a high mortality rate. Jayson and Jones, Mcavin et al, and Watson and Hayreh also suggested that these aggressive destructive ocular lesions herald systemic vasculitis and require aggressive immunosuppressive treatment. Azathioprine, methotrexate, and ciclosporin have been used with varying success, but cyclophosphamide has been widely used in destructive ocular inflammatory conditions and has a well established role in treating systemic vasculitis. Systemic and local steroids are used but we have concerns about the reduction in cornea healing, and steroids alone do not alter mortality.

We found no incidence of infection or immunosuppressive complication. The vision of all patients was preserved and, to date, none of the patients who received intravenous cyclophosphamide have presented with evidence of systemic vasculitis and this is probably due to the use of immunosuppressive treatment.

We cannot emphasise enough that this is a condition that should be managed by both a rheumatologist and an ophthalmologist, both of whom need to be aware of the acute ocular concerns as well as the long term consequences with associated high mortality in those who do not receive immunosuppressive treatment.

with Behçet’s disease, to control the acute phase of the inflammatory process. It will be possible to discuss a further shift to standard immunosuppressive drugs when the acute phase of the disease has been controlled. Furthermore, association of infliximab and other standard immunosuppressive drugs allows the anti-TNF dosage to be decreased. This should be taken into consideration to prevent immunogenicity against the drug, inducing secondary resistance. Tapering of corticosteroids and discontinuation of immunosuppressive drugs must be achieved cautiously, in order to prevent further relapses.

It is difficult to consider infliximab as a chronic long term monotherapy. Owing to the rapidity of action, it has to be administered earlier in the course of the disease, to spare steroids and to facilitate the action of other immunosuppressive drugs. Induction treatment with infliximab has an increased likelihood of a sustained response over a long term period if infusions are continued every 8 weeks. However the optimal dose, rhythm, and duration of infliximab infusions need to be standardised. Our data indicate the need for larger controlled trials before drawing up further adapted guidelines.

Systemic mastocytosis: a rare cause of osteoporosis and its response to bisphosphonate treatment

A Y N Lim, A J K Ostor, S Love, A J Crisp

Abstract

Mastocytosis comprises a heterogeneous group of disorders of mast cell proliferation. Infiltration of multiple organs by mast cells may occur, including skin and bone, with cutaneous and systemic variants being well described. There are few reports of the treatment of osteoporosis, a secondary manifestation of systemic mastocytosis (SM). We undertook a retrospective analysis of six patients with osteoporosis associated with SM treated with bisphosphonates.

CASE REPORTS

The mean age of the patients was 58 years (range 40–70) and the mean duration of SM was 8 years (range 3–13). All patients had a past history of urticaria pigmentosa and had presented to their general practitioner with back pain. Four patients had vertebral crush fractures on plain radiography. Isotope bone scans in the remaining two patients showed diffuse skeletal uptake consistent with marrow infiltration. Bone marrow biopsy in all patients confirmed mast cell infiltration. All patients had mast cell mediator related symptoms (flushing, wheezing, diarrhoea with abdominal pain, pruritus, bone pain) and raised total serum tryptase levels persistently. Tryptase levels correlate with the clinical severity of SM, and we used this to monitor disease activity.

Treatment was started with bisphosphonates (annual intravenous pamidronate followed by alendronate in five patients, alendronate only in the sixth patient). No further fractures developed despite absence of specific treatment for mast cell proliferation. All patients had a subjective improvement in pain after bisphosphonate treatment. Hologic bone mineral density (BMD) measurements were assessed at baseline and at 1–2 yearly intervals thereafter. BMD in the lumbar spine rose in all patients from baseline; two patients (Nos 1 and 2) were excluded owing to multiple lumbar vertebral fractures. Total hip BMD rose in three patients and stabilised in the other three (table 1).

DISCUSSION

Disorders of mast cells, derived from the multipotent haematopoietic stem cell are rare. Cutaneous mastocytosis without systemic involvement manifests in childhood as urticaria pigmentosa and spontaneous regression occurs during puberty. Symptoms of SM are related to the release of mast cell mediators, including histamine, prostaglandins, leukotrienes, and proteases, with bone pain occurring frequently. The radiological findings in SM include diffuse osteoporosis with vertebral fractures and/or a combination of osteosclerotic and osteolytic lesions, primarily affecting the axial skeleton and ends of long bones. Solitary lesions (mastocytomas) may cause localised pain.

The cellular and pathophysiological mechanisms leading to osteoporosis in SM are poorly understood. Mast cells infiltrating bone marrow may have an inhibitory effect on the coupling of bone formation and resorption, with the balance in favour of the latter. It is unlikely that bone resorption is caused directly by mast cell release of heparin, prostaglandin D$_2$, and tryptase. SM has been reported to account for a greater than expected cause of osteoporosis in the younger population. Indeed, back pain secondary to osteoporotic vertebral fractures may be the major presenting symptom of SM. BMD stabilised without the occurrence of further fractures in our patients. Fracture reduction is due not only to inhibition of osteoclasts by bisphosphonates but their ability to reduce the activation frequency and birth rates of new bone remodelling units and to enhance osteon mineralisation. Musculoskeletal pain in mastocytosis may be present in up to 28% of patients and is difficult to manage. Interestingly, our patients reported improvement in bone pain after bisphosphonate treatment.

In conclusion, SM, although rare, should be included in the differential diagnosis of idiopathic osteoporosis because of its...
significant morbidity. Bisphosphonates are effective in SM for osteoporosis and have a role in the associated refractory bone pain.

Frostbite arthritis

J E Kahn, O Lidove, J D Laredo, O B Étry

A 46 year old black woman, born in Haiti, was admitted in 1999 owing to bilateral and symmetric arthritis of the hands. Her past history was unremarkable. She had lived in New York in the 1970s, where she sustained an episode of severe frostbite in 1977 while staying outside for 1 hour at a temperature of −20°C without protection. Frostbite affected all fingers but not the thumbs, requiring admission to hospital for 11 days (amputation of some fingers was discussed at this time).

She had complained about arthritis affecting the interphalangeal (IP) joints since 1994, without extra-articular involvement or fever. Progressive joint deformations appeared at this time. Clinical examination was normal except for proximal IP joint deformation.

Routine laboratory tests, immunological tests (antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, complement), seric tests (HIV, HTLV-I, TPHA-VDRL), antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, complement), seric tests (HIV, HTLV-1, TPHA-VDRL), appeared at this time. Clinical examination was normal except for proximal IP joint deformation.

Clinical examination was normal except for proximal IP joint deformation.

Figure 1

Figure 1 Erosive arthritis with subchondral osteosclerosis and large punched-out cystic defects affecting all proximal and some of the distal IP joints.
DISCUSSION
Initially described in the military population, frostbite is also common in people with psychiatric disturbance, intoxication, or unplanned circumstances leading to cold exposure (as in our case).

Clinical and radiological changes mimic those of osteoarthritis.1–4 A clinical and radiological idiosyncrasy is the preservation of both thumbs and metacarpophalangeal joints.1–4 Sparing of the thumb is characteristic, although not invariable, and can be attributed to clenching of the fist with the thumb clasped in the palm during cold exposure. The presence of large subchondral cysts in our patient, probably consecutive to bone infarcts, helps in differentiating frostbite arthritis from osteoarthritis. Early diagnosis can be suspected by 99mTc scintigraphy in the first days after exposure to cold, but hyperfixation could persist several years after, as reported in this observation.

The time intervals between frost injury and clinical symptoms are variable—from 3 to 10 years (17 years in our case). Frostbite results from exposure to cold air usually at a temperature below −13°C (8°F). The development and progression of frostbite injuries are directly related to abnormality in circulation (thrombosis, vasoconstriction).

A pathophysiological study has shown marked similarities in inflammatory processes between thermal burns and ischaemia/reperfusion injury due to cold exposure. Evidence of the role of thromboxanes and prostaglandins has resulted in more active approaches to the medical treatment of frostbite wounds.5 Initial treatments are debatable: vasodilators, hyperbaric oxygen, thrombolysis, or surgery, when necessary. At a chronic stage, treatment of frostbite arthritis with NSAIDs or steroids at low dosage has been suggested. Clodronic acid was proposed because of the known anodyne effect of bisphosphonates in some cases of rheumatism, but, to our knowledge, there is no report of use of bisphosphonates in frostbite arthritis.

In conclusion, patients with distal arthritis should be carefully questioned for a history of exposure to cold, and frostbite arthritis should be considered in the differential diagnosis of unexplained, seronegative arthritis of hands. Clinical and radiological changes mimicked those of osteoarthritis, but the presence of giant subchondral cysts, unusual in osteoarthritis, may suggest the diagnosis.
