EXTENDED REPORT

Association of circulating miR-223 and miR-16 with disease activity in patients with early rheumatoid arthritis

Background Identification of parameters for early diagnosis and treatment response would be beneficial for patients with early rheumatoid arthritis (ERA) to prevent ongoing joint damage. miRNAs have features of potential biomarkers, and an altered expression of miRNAs was shown in established rheumatoid arthritis (RA).

Objective To analyse RA associated miRNAs in the sera of patients with early rheumatoid arthritis to find markers of early disease, clinical activity or predictors of disease outcome.

Methods Total RNA was isolated from whole sera in ERA patients (prior to and after 3 and 12 months of therapy with disease modifying antirheumatic drugs), in patients with established RA and in healthy controls (HC) using phenol–chloroform extraction. Expression of miR-146a, miR-155, miR-223, miR-16, miR-203, miR-132 and miR-124a was analysed by TaqMan Real Time PCR.

Results From all analysed miRNAs, levels of miR-146a, miR-155 and miR-16 were decreased in the sera of ERA patients in comparison with established RA. A change in circulating miR-16 in the first 3 months of therapy was associated with a decrease in DAS28 in long term follow-up in ERA (p=0.002). Levels of circulating miR-223 in treatment naive ERA correlated with C reactive protein (p=0.008), DAS28 (p=0.031) and change in DAS28 after 3 months (p=0.003) and 12 months (p=0.011) of follow-up. However, neither miR-16 nor miR-223 could distinguish ERA from HC.

Conclusions Differential expression of circulating miR-146a, miR-155 and miR-16 in the sera of ERA patients may characterise an early stage of the disease. We suggest miR-223 as a marker of disease activity and miR-16 and miR-223 as possible predictors for disease outcome in ERA.

INTRODUCTION

Rheumatoid arthritis (RA) is a systemic, inflammatory, autoimmune disorder with progressive articular damage that may result in severe lifelong disability. A considerable number of RA patients develop severe disability early in the disease.1 Studies have shown a beneficial effect of early treatment on clinical outcome and reduction in joint damage that prevents irreversible joint destruction and disability.2–4 In addition, a delay of a few months from the onset of symptoms to the institution of therapy decreases the ability of the traditional single drug strategy to induce remission in early rheumatoid arthritis (ERA).5–7 Therefore, in order to define patients at earlier stages of the disease who would benefit from early effective intervention, new RA classification criteria were developed.8 However, while some patients profit from initial monotherapy, others fail to demonstrate clinical or radiological responses, even to combination therapy.9 Until now, several predictors of response to disease modifying antirheumatic drugs (DMARD) and biological treatments such as cytokine profiles or gene expression analysis have been described but are either impractical or lack specificity to be adopted in daily clinical practice.9,10 Therefore, it is important to find parameters that identify patients with early arthritis and to find predictors of treatment response in ERA to optimise individual management of early arthritis based on the expected disease course and to prevent over or under treatment.9–10

miRNAs are short single stranded non-coding RNAs involved in the post-transcriptional regulation of gene expression.11 Altered expression of miRNAs has been described under various pathological conditions, including rheumatic and other autoimmune diseases.12,13 We and others reported that miR-146a, miR-155 and miR-203 are overexpressed while miR-124a appeared suppressed in RA synovial fibroblasts.14–17 Dysregulation of miR-146a, miR-155, miR-223, miR-16 and miR-132 was observed in immune cells derived from patients with RA.14 18–22 As miRNAs are stably present in cell free form in body fluids and circulating miRNAs were shown to have signatures related to tumour classification and disease progression, they are becoming new candidate biomarkers for diagnosis and prognosis in different diseases.23–25 Although expression of several miRNAs has recently been analysed in plasma and synovial fluid of patients with established RA and osteoarthritis,26 there are no reports to date on the important phase of ERA.

The aim of our study was to analyse the profile of selected RA related cell free circulating miRNAs in the sera of patients with ERA prior to and after therapy with DMARD, in established RA and in healthy controls (HC). Using this approach, we hoped to identify potential tools distinguishing early and late phases of the disease, markers of
clinical activity or predictors of disease outcome. In addition, we analysed intracellular expression of these miRNAs in synovial fibroblasts from patients with ERA.

MATERIAL AND METHODS
Collection of sera and characteristics of patients with RA
Sera and clinical details from 34 patients with ERA who fulfilled the 2010 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) classification criteria for RA with a symptom duration <8 months were obtained at the 2010 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) classification criteria for RA. Sera from 28 patients with established treated RA of disease duration 9.28±6.52 years who fulfilled the 1987 revised ACR criteria for the classification of RA were obtained from both the Department of Rheumatology, University Hospital, Zurich, and the Institute of Rheumatology, Prague. Clinical characteristics of the patients and the 16 HC (University Hospital, Zurich) are shown in table 1. Written informed consent was obtained from all participants, and the study was approved by the local ethics committees.

Synovial fibroblasts from patients with inflammatory arthritis
Synovial fibroblasts (SF) were isolated from synovial tissues obtained during ultrasound guided synovial tissue biopsy (University of Birmingham, UK). Synovial tissue samples were taken from patients with untreated ERA (n=7) with a disease duration <13 months who met the 1987 ACR criteria, from patients with knee pain of non-inflammatory origin (n=9) and from patients with resolving arthritis different from RA (n=14). Written informed consent was obtained from each donor, and the study was approved by the local ethics committee. For a detailed description of the methods, see online supplementary material.

RESULTS
Circulating miRNAs are differentially expressed in the sera of patients with ERA and established RA
As several miRNAs have been reported to show altered expression in immune cells, SF, plasma or synovial fluid from patients with established RA, we anticipated dysregulation of circulating miRNAs at the onset of the disease in comparison with the established state. Considering circulating miRNAs as potential biomarkers, their analysis in sera would be of interest due to easy accessibility of samples for clinical use. Therefore, analysis of RA related miR-146a, miR-155, miR-203, miR-124a, miR-223, miR-16 and miR-132 in sera was performed in patients with treatment naive ERA, established treated RA and HC.

Levels of miR-146a were significantly lower in the sera of patients with ERA (dCt 0.44±0.93) in comparison with patients with established RA (dCt 1.20±1.00, p<0.01) or HC (dCt 1.27±1.07, p<0.05). There was no difference between established RA and HC (figure 1A). Circulating miR-155 in ERA patients (dCt −6.31±1.05) showed comparable levels with HC (dCt −5.84±1.24) while it significantly differed from patients with established RA who demonstrated higher levels of miR-155 (dCt −4.68±1.86, p<0.001) (figure 1B). Similarly, miR-16 was

were therefore excluded from further analysis (data not shown). ±0.77 for miR-223). MiR-124a and miR-203 in sera were ERA, established RA and HC (dCt than in HC but did not reach statistical signi 5.23±1.25). The levels of miR-16 in established RA were higher 6.10±1.22, p<0.001) while it was comparable with HC (dCt ERA (dCt 4.93±0.91) than in patients with established RA (dCt 4.34±0.78) significantly decreased in comparison with both baseline (p<0.05) and M3 (p<0.001, figure 2A). In addition, the increase in miR-16 at M3 was verified by an independent method using TaqMan Low Density Arrays cards (TLDAs) (3.768-fold change, see online supplementary table 1). The effect of different treatment modalities on levels of miR-16 is given in the online supplementary table 2.

Higher levels of miR-16 at baseline correlated with a greater improvement in disease activity, represented by a larger decrease in DAS28 from baseline to M3 (r=−0.478, p=0.008) (figure 2B). Similarly, levels of miR-16 at M3 correlated with a change in disease activity DAS28 from M3 to M12 (r=−0.335, p=0.047) (figure 2C). Most importantly, the change in levels of miR-16 from baseline to M3 were negatively associated with the change in DAS28 from M3 to M12 (r=−0.519, p=0.002) (figure 2D) suggesting that the increase in circulating miR-16 within the first 3 months after treatment initiation was followed by the decrease in disease activity in the subsequent 9 months. Interestingly, levels of miR-16 at baseline negatively correlated with levels of anticitrullinated protein antibodies (ACPA) (r=−0.365, p=0.037). However, levels of miR-16 did not correlate with C reactive protein (CRP), erythrocyte sedimentation rate or IgG, IgM or IgA rheumatoid factors (RF) at baseline, M3 or M12 (data not shown).

Although differentially expressed in ERA sera in comparison with established RA sera, levels of circulating miR-16 showed no association with disease activity in established RA (data not shown).

MiR-223 as a marker of disease activity in treatment naïve ERA and its association with disease outcome during short and long time follow-up Levels of miR-223 were found to be decreased by 17.65% in 24/34 ERA patients 3 months after treatment initiation. However, in the group of all ERA patients, the change in levels of miR-223 at M3 in comparison with baseline did not reach statistical significance (dCt 5.67±0.104 vs 5.12±0.91). In fact, after 12 months of treatment, levels of miR-223 (dCt 5.12±0.91) significantly decreased in comparison with levels at baseline (p<0.001) and at M3 (p<0.01) (figure 3A). Further analysis using TLDAs showed no change in levels of miR-223 at M3 (1.065-fold change) but confirmed the decreased levels of miR-223 at M12 (0.692-fold change, see online supplementary table 1). The effect of different treatment modalities on levels of miR-223 is given in the online supplementary table 2.

In ERA prior to treatment initiation, levels of miR-223 positively correlated with CRP (r=0.519, p=0.008 figure 3B) and with DAS28 (r=0.389, p=0.031) (figure 3C) at baseline. Importantly, levels of miR-223 at baseline correlated with the decrease in DAS28 from baseline to M3 (r=−0.522, p=0.003) (figure 3D) as well as from baseline to M12 (r=−0.460, p=0.011) (figure 3E). Moreover, the greater decrease in levels of miR-223 from baseline to M12, the more improvement in

Change in circulating miR-16 during therapy is associated with decreasing disease activity Subsequently, the effect of therapy with DMARDs on levels of miRNAs was explored in ERA patients. Also, the association of circulating miRNAs with markers of disease activity in ERA and established RA was evaluated. Follow-up within 3 months (M3) after initiation of therapy appeared to be a very important time point with respect to clinical response and prediction of outcome at 12 months (M12).

Levels of miR-16 increased by 34.31% in 24/34 ERA patients after 3 months of therapy. Although miR-16 was the only miRNA analysed in our study, showing a trend towards higher levels after 3 months of treatment with DMARDs (dCt 4.93±0.91 vs 5.71±1.27), it did not reach statistical significance in the whole group of ERA patients. However, levels of miR-16 at M12 (dCt 3.85±1.37) significantly decreased in comparison with both baseline (p<0.05) and M3 (p<0.001, figure 2A). In addition, the increase in miR-16 at M3 was verified by an independent method using TaqMan Low Density Arrays cards (TLDAs) (3.768-fold change, see online supplementary table 1). The effect of different treatment modalities on levels of miR-16 is given in the online supplementary table 2.

Higher levels of miR-16 at baseline correlated with a greater improvement in disease activity, represented by a larger decrease in DAS28 from baseline to M3 (r=−0.478, p=0.008) (figure 2B). Similarly, levels of miR-16 at M3 correlated with a change in disease activity DAS28 from M3 to M12 (r=−0.335, p=0.047) (figure 2C). Most importantly, the change in levels of miR-16 from baseline to M3 were negatively associated with the change in DAS28 from M3 to M12 (r=−0.519, p=0.002) (figure 2D) suggesting that the increase in circulating miR-16 within the first 3 months after treatment initiation was followed by the decrease in disease activity in the subsequent 9 months. Interestingly, levels of miR-16 at baseline negatively correlated with levels of anticitrullinated protein antibodies (ACPA) (r=−0.365, p=0.037). However, levels of miR-16 did not correlate with C reactive protein (CRP), erythrocyte sedimentation rate or IgG, IgM or IgA rheumatoid factors (RF) at baseline, M3 or M12 (data not shown).

Although differentially expressed in ERA sera in comparison with established RA sera, levels of circulating miR-16 showed no association with disease activity in established RA (data not shown).

MiR-223 as a marker of disease activity in treatment naïve ERA and its association with disease outcome during short and long time follow-up Levels of miR-223 were found to be decreased by 17.65% in 24/34 ERA patients 3 months after treatment initiation. However, in the group of all ERA patients, the change in levels of miR-223 at M3 in comparison with baseline did not reach statistical significance (dCt 5.67±0.104 vs 5.12±0.91). In fact, after 12 months of treatment, levels of miR-223 (dCt 5.12±0.91) significantly decreased in comparison with levels at baseline (p<0.001) and at M3 (p<0.01) (figure 3A). Further analysis using TLDAs showed no change in levels of miR-223 at M3 (1.065-fold change) but confirmed the decreased levels of miR-223 at M12 (0.692-fold change, see online supplementary table 1). The effect of different treatment modalities on levels of miR-223 is given in the online supplementary table 2.

In ERA prior to treatment initiation, levels of miR-223 positively correlated with CRP (r=0.519, p=0.008 figure 3B) and with DAS28 (r=0.389, p=0.031) (figure 3C) at baseline. Importantly, levels of miR-223 at baseline correlated with the decrease in DAS28 from baseline to M3 (r=−0.522, p=0.003) (figure 3D) as well as from baseline to M12 (r=−0.460, p=0.011) (figure 3E). Moreover, the greater decrease in levels of miR-223 from baseline to M12, the more improvement in
DAS28 was observed after 12 months of therapy ($r=0.483$, $p=0.006$) (figure 3F). In contrast with significant correlations of miR-223 with disease activity in ERA patients before treatment, levels of miR-223 did not correlate with parameters of disease activity (DAS28 or CRP), or levels of ACPA, IgG, IgM or IgA RF at M3 or M12 after initiation of therapy (data not shown).

In established RA, levels of miR-223 showed no correlation with disease activity (data not shown).

In addition, neither miR-146a nor miR-155 or miR-132 showed any association with disease activity in patients with ERA at baseline, M3 or M12, or in patients with established RA or any change in expression after therapy in ERA (data not shown).

Decrease in levels of miR-223 in sera follows change in peripheral leucocyte count

We found a significant correlation between baseline levels of miR-223 and peripheral leucocyte (PL) count in patients with ERA ($r=0.459$, $p=0.007$) (figure 4A). Therefore, we were interested in whether the change in levels of miR-223 after treatment followed the change in PL count. In fact, the larger decrease in miR-223 between baseline and M3 positively correlated with the decrease in PL count between these two time points ($r=0.397$, $p=0.025$) (figure 4B). Also, the changes in levels of miR-223 and PL count within the whole period of 12 months correlated significantly ($r=0.621$, $p=0.0001$) (figure 4C). This suggests that the decrease in miR-223 in the sera of ERA patients after therapy is very likely attributable to the change in the number of PLs.

Expression of miRNAs in synovial fibroblasts from patients with ERA

Based on different levels of miRNAs in ERA reported here, we anticipated dysregulation of miRNAs in SF from patients with ERA. Therefore, expression of miR-146a, miR-155, miR-203, miR-124a, miR-223, miR-16 and miR-132 was analysed in isolated SF cultured in vitro.

In contrast with differences in levels of miRNAs observed in sera, there were no significant differences in expression of miRNAs analysed in our study among SF from patients with ERA, resolving arthritis of different disease entities as an example of non-RA arthritis and controls with non-inflammatory arthralgia (see online supplementary figure 2).

DISCUSSION

RA is a chronic inflammatory disease characterised by progressive joint destruction. We and others have shown that altered expression of miRNAs in immune and resident cells involved in the pathogenesis of RA contributes to maintenance of pathognomonic features typical of RA.13 For example, miR-155 and miR-146a are induced in response to inflammatory stimuli and are overexpressed in RA SF in comparison with osteoarthritis SF.14 18 30 MiR-155 acts as a positive regulator and miR-146a as a negative regulator of inflammation in RA, as shown in vivo.18 31 32 MiR-223 was shown to be overexpressed in synovial tissue of RA patients and, importantly, silencing of miR-223 reduced disease severity in experimental arthritis.33 The evidence of high stability of miRNAs in body fluids due to incorporation into microvesicles or stabilisation in complexes with RNA binding proteins (Argonaute 2, high density lipoproteins, nucleophosmin 1) and their easy accessibility make miRNA
ideal biomarkers. Moreover, changes in the number of miRNAs originating from blood cells or tissues and their specific profiles influenced by pathophysiological conditions, such as sepsis, have been described previously. Based on these data, we anticipated that levels of circulating miRNAs in sera would be different in patients with ERA and established RA.

We report here for the first time reduced levels of miR-146a, miR-155 and miR-16 in the sera of patients with ERA in comparison with patients with established RA. Levels of these miRNAs were comparable between patients with established RA and HC, similar to the data published by Murata et al., except for miR-132 that was shown to be lower in RA than in HC. Although intracellular expression of miR-146a and miR-155 was shown to be induced by the proinflammatory milieu in vitro, it is possible that cell-free circulating miRNAs in sera do not necessarily reflect levels in the intracellular compartment. In fact, release of miRNAs may be selective due to the existence of a cellular selection mechanism for miRNA release and therefore the extracellular and cellular miRNA profiles may differ. Secretory cell free miRNAs were shown to transfer inhibitory signals to recipient cells. Although the functional role and impact of circulating miRNAs in living organisms remains currently unknown, we speculate that in ERA, miR-146a and miR-155 may be extensively taken up by recipient cells where they exert their regulatory activity. We propose that low levels of miR-146a, miR-155 and miR-16 in ERA may represent the early phase of RA. We hypothesise that progression of disease severity, disease duration, effect of treatment or other yet unknown factors can modulate levels of circulating miRNAs in established RA.

MiR-16 was reported to be overexpressed in peripheral blood mononuclear cells of RA patients with active disease in comparison with RA patients with low disease activity or with HC. We showed here that the higher levels of miR-16 in the sera of treatment naïve patients with ERA correlated with better improvement in disease activity during the 3 months of follow-up. This is important because most clinical responses in ERA are seen in the first 3 months of therapy, as shown in table 1. In addition, change in levels of circulating miR-16 within the first 3 months after initiation of therapy is associated with disease outcome in the following 9 months.
MiR-223 was recently demonstrated to be upregulated in peripheral T cells from patients with early as well as established RA compared with HC, but no correlation of miR-223 in these cells with DAS28, CRP, RF or ACPA was found in these patients. In addition, no differences in expression of miR-223 in T cells were observed in untreated RA patients and patients. 40 Although not differentially expressed in the sera of ERA and RA patients, we suggest circulating miR-223 may become a useful tool to predict disease outcome in patients with ERA. Moreover, monitoring levels of miR-16 and miR-223 may become a useful test to predict disease outcome in patients with ERA.

In conclusion, we have shown here for the first time low expression of miR-146, miR-155 and miR-16 in the sera of patients with early in comparison with established RA. Although further studies in larger patient cohorts are needed, our data support circulating miR-223 as a marker of disease activity in patients with treatment naïve ERA. Moreover, monitoring levels of miR-16 and miR-223 may become a useful test to predict disease outcome in patients with ERA.
