CLINICAL SCIENCE

Diagnosis of osteoporosis in statin-treated patients is dose-dependent

Michael Leutner, Caspar Matzhold, Luise Bellach, Carola Deischinger, Jürgen Harreiter, Stefan Thurner, Peter Klimek, Alexandra Kautzky-Willer

ABSTRACT

Objective: Whether HMG-CoA-reductase inhibition, the main mechanism of statins, plays a role in the pathogenesis of osteoporosis, is not entirely known so far. Consequently, this study was set out to investigate the relationship of different kinds and dosages of statins with osteoporosis, hypothesising that the inhibition of the synthesis of cholesterol could influence sex-hormones and therefore the diagnosis of osteoporosis.

Methods: Medical claims data of all Austrians from 2006 to 2007 was used to identify all patients treated with statins to compute their daily defined dose averages of six different types of statins. We applied multiple logistic regression to analyse the dose-dependent risks of being diagnosed with osteoporosis for each statin individually.

Results: In the general study population, statin treatment was associated with an overrepresentation of diagnosed osteoporosis compared with controls (OR: 3.62, 95% CI 3.55 to 3.69, p<0.01). There was a highly non-trivial dependence of statin dosage with the ORs of osteoporosis. Osteoporosis was underrepresented in low-dose statin treatment (0–10 mg per day), including lovastatin (OR: 0.39, CI 0.18 to 0.84, p<0.05), pravastatin (OR: 0.68, 95% CI 0.52 to 0.89, p<0.01), simvastatin (OR: 0.70, 95% CI 0.56 to 0.86, p<0.01) and rosvastatin (OR: 0.69, 95% CI 0.55 to 0.87, p<0.01). However, the exceeding of a 20 mg threshold for atorvastatin (OR: 1.64, 95% CI 1.31 to 2.07, p<0.01), and the exceeding of a 20 mg threshold for atorvastatin (OR: 1.78, 95% CI 1.41 to 2.23, p<0.01) and for rosvastatin (OR: 2.04, 95% CI 1.31 to 3.18, p<0.01) was related to an overrepresentation of osteoporosis.

Conclusion: Our results show that the diagnosis of osteoporosis in statin-treated patients is dose-dependent. Thus, osteoporosis is underrepresented in low-dose and overrepresented in high-dose statin treatment, demonstrating the importance of future studies’ taking dose-dependency into account when investigating the relationship between statins and osteoporosis.

INTRODUCTION

Osteoporosis is a chronic disease characterised by a reduced bone mineral density (BMD) induced by an imbalance in osteoblastic and osteoclastic bone formation and resorption. Due to the elevated fracture risk, osteoporosis can have detrimental effects on a patient’s quality of life and is associated with a higher mortality and morbidity as well as being an economic burden. By now, numerous studies about osteoporosis and its treatment have been conducted—many of which revolve around the question whether statins affect bone metabolism. Statins play a crucial role in the management of hypercholesterolemia, which makes them a commonly used drug. Actual guidelines for the treatment of hypercholesterolemia in high-risk patients suffering from cardiovascular disease (CVD) or diabetes have been issued, recommending cholesterol levels to be as low as possible. Therefore, due to the sheer number of patients under statin therapy, research on the connection between statin usage and osteoporosis risk is of great importance. In particular, the underlying pathophysiological mechanisms of a possible osteoprotective effect of statins have yet to be fully established.

are sparse. Consequently, the present study seeks to investigate
the relationship between different kinds and dosages of statins
and osteoporosis and to shed light on the controversy regarding
the relationship between statin treatment and the diagnosis of
osteoporosis in a nationwide population-based study.

STUDY DESIGN AND METHODS
We conducted a cross-sectional retrospective analysis of the
total Austrian population using a consolidated administrative
research data base.18

Patient population
Our data include all Austrians with health claims (roughly 97% of
the population) for which data on all main and side diag-
noses from hospital stays and all prescriptions of drugs with
costs that exceed a prescription charge of EUR 4.70 is available.
We included patients with uniquely identifiable age and sex who
were alive during the entire observation period from January
2006 to December 2007 (n = 7 945 775). Patients born in these
years or with age >90 years were excluded to gain a more
homogenous group of patients. The obtained cohort consisted of
7 897 449 patients (male = 3 702 572; female = 4 194 877).
Information on prescriptions was available in the Anatomical Therapeu-
tic Chemical (ATC) Classification System codes; to identify
patients being diagnosed with osteoporosis, main and side diag-
noses from hospital stays were extracted as International Classi-
fication of Diseases, 10th revision (ICD10) codes. Patients with
a main or side diagnosis from the range M80–M82 (including
M80: ‘Osteoporosis with current pathological fracture’; M81:
‘Osteoporosis without current pathological fracture’ and M82:
‘Osteoporosis in diseases classified elsewhere’ (defined as osteo-
porosis in multiple myelomatosis or endocrine disorders) were
classified as osteoporosis patients. We additionally conducted
a sensitivity analysis to control for occurrences of rheumatoid
arthritis (ICD10 code M06), ischaemic heart diseases (any code
from the range I20–I25), diseases or arteries including arterio-
les and capillaries (I70–I79), stroke (I63, I64), diabetes (E10, E11),
chronic renal insufficiency (N17–N19), nicotine dependency
(F17), overweight and obesity (E65–E68), chronic obstructive
pulmonary disease (J44), asthma (J45) and Crohn’s disease
(K50).

Identifying patients with statin treatment
We identified all patients who had at least one prescription of
any of the seven statins available on the market during the obser-
vation period: Simvastatin (ATC-code: C10AA01), Lovastatin
(ATC-code: C10AA02), Pravastatin (ATC-code: C10AA03),
Fluvastatin (ATC-code: C10AA04), Atorvastatin (ATC-code:
C10AA05), Cerivastatin (ATC-code: A10AA06) and Rosuva-
statin (ATC-code: C10AA07). For these patients, we additionally
controlled for possible effects of other prescribed drugs including
49 different kinds of insulin-sparing or providing medication
(all ATC-codes starting with A10) and 3 fibrates (ATC-code:
C10AB02, C10B05, C10A×09).

For each medication, we tested if the patient was a regular
drug user or not. Only if a patient had a minimum of four
different prescription entries for a given drug, we identified him/
her as a valid drug user. As most health claims are filed on a
quarterly basis, four different prescription entries are equivalent
to a treatment regularly applied over 1 year. Medications with
less than 35 valid patients were excluded. The control group was
made up of all patients not treated with statins.

Average daily doses
The average daily dose of a given drug for each patient was
calculated as the amount of the drug (converted from defined
daily dose to mg) divided by the number of treatment days
that the patient did not spend in a hospital. Patients were then
grouped according to their average daily dose for each statin in
groups of >0–10 mg, >10–20 mg, >20–40 mg, >40–60 mg and
>60–80 mg.

Patient and public involvement
Patients were not involved in the study design. Details of the
ethical approval are provided in the online supplementary
material.

Statistical analyses
We computed age-specific and sex-specific ORs between statin
use and being diagnosed with osteoporosis. Multiple logistic
regression was used to investigate this association while
controlling for age, sex, dosage and prescription of other medi-
cations (drugs used in diabetes and fibrates). Next to age and sex,
the independent variables in the regression included the dosage
category for each type of statin or other medication as a catego-
rical variable. Patients were assigned a categorical variable for
each statin according to their average daily dose in milligrams.
We controlled for other medications (20 glucose lowering drugs,
including metformin; 3 fibrates) by introducing binary dummy
variables for whether the patient fulfilled all criteria to be consid-
ered a valid drug user or not (see above). Goodness of fit of
the regression models was evaluated by the adjusted R-squared
statistic; the variance inflation factor (VIF) was used to test for
multicollinearity.

RESULTS
Baseline characteristics
We identified 353 502 statin-treated patients (175 506 males,
177 996 females) out of which 11 701 patients (1765 males,
9936 females) were diagnosed with osteoporosis (for a detailed
description of the osteoporotic population, see also online supple-
cmental tables S1 and S2). The control group (no statin
exposure) consisted of 7 543 947 patients (3 527 066 males,
4 016 881 females), including 68 699 patients (10 410 males,
58 289 females) diagnosed with osteoporosis. Table 1 presents
the results of a sex-matched and age-matched cohort analysis
of statin users in comparison to non-statin users and shows that
statin users presented more often with a diagnosis of CVD, renal
failure, nicotine dependence, overweight and obesity and were
treated more often with antidiabetics.

Sex-specific comparison of the diagnosis of osteoporosis
Within the whole study population, our results show that women
are at a higher risk of being diagnosed with osteoporosis when
compared with men (OR: 5.08, 95% CI 4.98 to 5.18, p<0.01; see
also online supplementary table S3).

Comparison of the diagnosis of osteoporosis between
patients with and without statin treatment
In the present analysis, the diagnosis of osteoporosis was more
prevalent in patients of any age treated with statins when
compared with control subjects without statin treatment (OR:
3.62, 95% CI 3.55 to 3.69, p<0.01). In a sex-specific analysis,
the diagnosis of osteoporosis was overrepresented in both statin-
treated females (OR(f): 3.90, 95% CI 3.81 to 3.98, p<0.01) and
males (OR(m): 3.35, 95% CI 3.18 to 3.52, p<0.01). Therefore,
the ORs for females were significantly increased with respect to males (p<0.01; see also online supplementary table S3). After stratifying the patients by their age in 10-year-intervals, we obtained similar results (osteoporosis being overrepresented in statin-treated individuals with significantly stronger effects in females than males) (see figure 1 and online supplementary table S3). In addition, figure 1 presents that in the age-class of 40–50 years, the relationship between statin treatment and increased odds of osteoporosis is stronger than in all other age groups.
R-squared statistics from the range 0.71–0.96 (see table 2 and online supplementary table S5). To test for multicollinearity, we considered the VIF for each variable and found the maximum value to be 4.21, indicating that multicollinearity is not an issue in the data (see table 2 and online supplementary table S5).

**Sex-specific analysis**

In a sex-specific analysis, the obtained results could be confirmed with slight differences as described in detail in the online supplementary material (see online supplementary table S5 and figure S1).

**DISCUSSION**

The aim of the present study was to investigate the relationship of statin therapy with osteoporosis. Our results showed that osteoporosis was overrepresented in statin-treated patients in the general study population. Thus, by splitting the study cohort in the different kinds of statins and dosages, there was a dose-dependent relationship with a diagnosed osteoporosis. Therefore, our results which showed that the diagnosis of osteoporosis was overrepresented in high-dose and underrepresented in low-dose statin treatment seem to be of great importance as they first show that it is important to analyse the different dosages and substances of statins.

Several studies have investigated whether HMG-CoA reductase inhibition, the main mechanism of statins, affects BMD. However, one of the main limitations of existing studies is that they did not investigate the relationship between the different kinds of statins (including potency and dosages) and the occurrence of osteoporosis in detail. A recent meta-analysis concluded that statin treatment had a tendency towards a positive effect on the reduction of fracture risk and marked improvement of BMD in statin-treated patients. A large meta-analysis conducted in Taiwan, including 45,342 patients in the statin cohort and 115,594 patients in the control cohort, stated that statin therapy correlates with a decreased risk of osteoporosis when taken daily over a longer period of time, however, also not accounting for the different types of statins and their dosages. In the present study, there was an increased risk of being diagnosed with osteoporosis in the general study population of statin-treated patients when compared with controls. However, the risk of being diagnosed with osteoporosis under statin-treatment decreased as a function of age, which could indicate that a longer statin treatment could be related to a lower occurrence of the diagnosis of osteoporosis. To the best of our knowledge, this is the first study which shows that it is important to consider the different kinds of substances and dosages when investigating the relationship of osteoporosis and statin therapy. Therefore, we could show that low-dose statin treatment with daily dosages lower or equal to 10 mg of pravastatin, lovastatin, simvastatin and rosuvastatin was related to an underrepresentation of osteoporosis. Lin et al also compared different types of statins but did not investigate the effects of different daily dosages of the statins on the prevalence rate of osteoporosis. Thus, in their study, they investigated the effect of statins on the probability of developing new-onset osteoporotic fractures (NOFs) and concluded that a therapy with rosuvastatin and atorvastatin was related to a risk reduction of NOFs, significantly stronger when compared with simvastatin treatment. However, our results demonstrate that it is important to analyse the different kinds and dosages of statins. Rejmark et al compared 124,655 fracture cases with 373,962 controls and found out that patients who had a fracture were less likely to use statins than the controls. In accordance with these findings, the present study also demonstrates an underrepresentation of osteoporosis in statin-treated patients, but only in patients on low dose statin therapy and not on high dose treatment of at least 1 year. Therefore, the increase of the dosage of statins was related to an overrepresentation of osteoporosis. A retrospective cohort study by Ward et al also omitted specifying the type of statin when comparing the fracture incidence of 6967 patients taking statins vs an equal number of controls. About one third of the patients received maximum dosages for simvastatin, pravastatin and atorvastatin, which were defined as 80 mg, and 40 mg for rosuvastatin. Although statins seem to decrease the risk of femoral neck fractures, there was no difference in the overall fracture risk when compared with the controls. In light of numerous publications presenting rather heterogenous results while pursuing the same research question, we attempted to propose additional explanations for the observed discrepancies.

VIF, variance inflation factor.
including a higher risk of bone fractures, is especially high in postmenopausal women. In the postmenopausal state, oestra
diol plays a crucial role in the maintenance of BMD and, thus, one has to keep in mind that oestrogens are cholesterol deri
vates and play a significant role in bone metabolism by inhibi
ting bone resorption. Thus, whether higher dosages of statins could inhibit the synthesis of sex hormones, via HMG-CoA-re
ductase inhibition, is of special interest, as we could show that an increase in the dosages of statins was related to an exaggerated increase and overrepresentation of diagnosed osteoporosis cases in the whole study population, and additionally significantly stronger in women than when compared with men. Women, especially due to lower oestrogen levels in the post menopause, are more likely to have an insufficient BMD. In men, free
testosterone levels are positively associated with higher levels of BMD and inversely related to bone turnover markers. The sex-specific differences in the pathogenesis of osteoporosis, a decreased activity of osteoblasts in men and an increased bone resorption due to a lack of oestrogen in women, would support the theory posed above. In mice models, statins have been
tested and the authors could prove that statin treatment was
also been presented in cell lines. In the Rotterdam study, the effect of statins in 4166 men on sexual hormones was investig
ated and the authors could prove that statin treatment was
related to lower serum total and non-sexual hormone-binding
globulin (SHBG)-bound testosterone levels. Lower testos
terone levels are associated with a decrease in BMD.
Taken together, these findings suggest a connection between sex hormone levels and BMD disease of osteoporosis.

There are limitations and strengths in the present study which have to be discussed. Limitations of our study include that the data extracted from the patient contingent only show the current dosage the patients are taking. However, only patients who had a statin treatment for a minimum of 1 year were included. Another limitation is that we could not confirm the diagnosis of osteoporosis, for example, with bone densitometry data, and that we had no access to relevant treatments such as corticoste
roids, hormonal replacement therapy or bisphosphonates. Ad
ditionally, one has to keep in mind that diseases such as CVD, which are commonly treated with statins, are related to other diseases and conditions such as diabetes, physical inactivity, nico
tine abuse or lack of hormone treatment in the menopause, all factors directly related to osteoporosis. A strength is that the compliance of the patients could be evaluated due to the data about the prescriptions of statins per year. Another strength is that the study investigated the general Austrian population and, therefore, the number of statin-treated patients is high.

CONCLUSION
In conclusion, our data suggest that osteoporosis is overrep
resented in high-dosage, but underrepresented in low-dosage statin treatment. Guidelines for cholesterol lowering therapies for prevention of cardiovascular complications advise to reduce plasma low-density lipoprotein (LDL-cholesterol) levels as low as 70 mg/dL in high risk populations. We propose that monitoring high-risk patients, that is, postmenopausal female patients under high-dosage statin therapy, might be useful in order to offer an individual therapy to prevent or treat osteoporosis.

Thus, larger and prospective studies with a focus on dosages of statins should be conducted in order to clarify the relationship with osteoporosis.
